Motorcycle Service Manual

Revised 5: Dec. 26, 1979 Ⓜ

Kawasaki Heavy Industries, Ltd. accepts no liability for any inaccuracies or omissions in this publication, although every possible care has been taken to make it as complete and accurate as possible. All procedures and specifications subject to change without prior notice, and may not apply to every country.

Foreword

This manual is designed primarily for use by motorcycle mechanics in a properly equipped shop although it contains enough detail and basic information to make it useful to the motorcycle user who desires to carry out his own basic maintenance and repair work. Since a certain basic knowledge of mechanics, the proper use of tools, and workshop procedures must be understood in order to carry out maintenance and repair satisfactorily; the adjustments, maintenance, and repair should be carried out only by qualified mechanics whenever the owner has insufficient experience or has doubts as to his ability to do the work so that the motorcycle can be operated safely.

In order to perform the work efficiently and to avoid costly mistakes, the mechanic should read the text, thoroughly familiarizing himself with the procedures before starting work, and then do the work carefully in a clean area. Whenever special tools or equipment is specified, makeshift tools or equipment should not be used. Precision measurements can only be made if the proper instruments are used, and the use of substitute tools may adversely affect safe operation of the motorcycle.

This manual is divided into the following chapters:

(1) Adjustment

The adjustment chapter gives the procedure for all adjustments which may become necessary periodically and which do not involve major disassembly.

(2) Disassembly

This chapter shows the best method for the removal, disassembly assembly, and installation which are necessary for maintenance and repair. Since assembly and installation are usually the reverse of disassembly and removal, assembly and installation are not explained in detail in many cases. Instead, assembly notes and installation notes are provided to explain special points.

(3) Maintenance and Theory of Operation

The procedures for inspection and repair are described in detail in this chapter. An explanation on the structure and functioning of each of the major parts and assemblies is given to enable the mechanic to understand better what he is doing.

(4) Appendix

The appendix in the back of this manual contains miscellaneous information, including special tool list, a torque table, a table for periodic maintenance, and a troubleshooting guide.

(5) Supplement

The maintenance and repair procedures that are unique to later year units since the first publication of the Service Manual, are explained in this chapter per one year unit.

Since the Service Manual is based on the first production units of the 1980 KE125-A7, there may be minor discrepancies between some vehicles and the illustrations and text in this manual. Explanations on major changes and additions pertaining to later year units will be added in the end of the supplement by a new edition, as required.

Adjustment

THROTTLE CONTROL CABLE

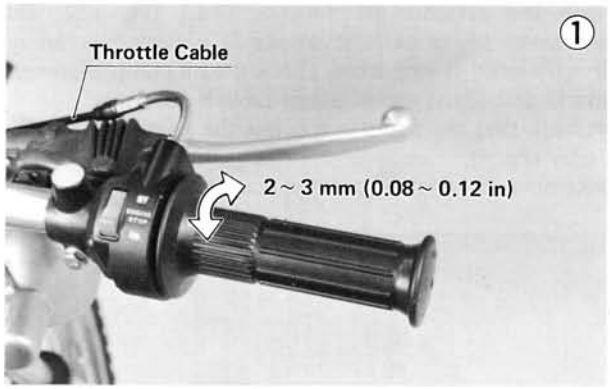
The throttle control cable is actually an assembly of three cables: the throttle cable, the carburetor cable, and the oil pump cable. The throttle cable runs from the throttle grip to the cable assembly junction where it connects to the carburetor cable, which leads to the carburetor, and the oil pump cable, which leads to the oil pump.

Since the throttle grip controls both the carburetor and the oil pump simultaneously, it is important that each cable be adjusted to its designated base position so that the quantity of oil and fuel/air mixture reaches the engine in the correct proportion at all throttle openings. Stretching of the cables creates excess play at the throttle grip and alters the base positions of the cables at the carburetor and the oil pump, necessitating periodic adjustment.

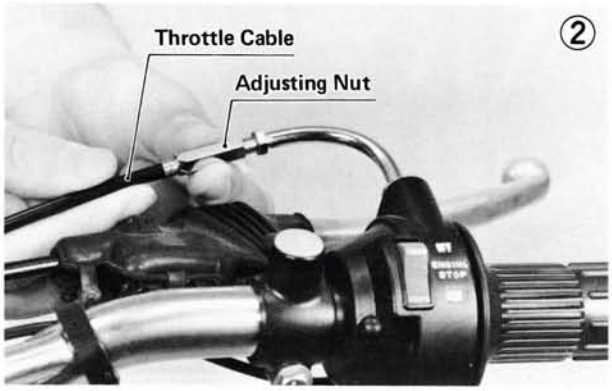
Throttle Cable

The throttle cable, connecting to both the carburetor cable and the oil pump cable, controls both the carburetor throttle valve and the oil pump lever. If there is too much play in the cable, neither the carburetor nor the oil pump will respond immediately when the grip is turned. Most of this excess play must be adjusted out. However, a small amount has to be left so that the steering movement will have no effect on the throttle valve or oil pump lever.

Check that the throttle grip has 2~3 mm (0.08~0.12 in) of play and turns smoothly. If there is too much or too little play, adjust the cable.



- Loosen the lock nut at the throttle grip end of the throttle grip cable.
- Turn the adjusting nut until the proper amount of throttle grip play is reached.
- Tighten the lock nut.



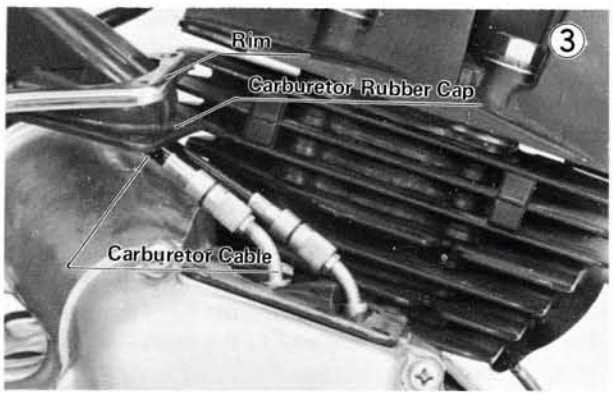
- Check the oil pump cable adjustment.
- If the throttle cable had insufficient play, adjust the carburetor cable.

Carburetor Cable

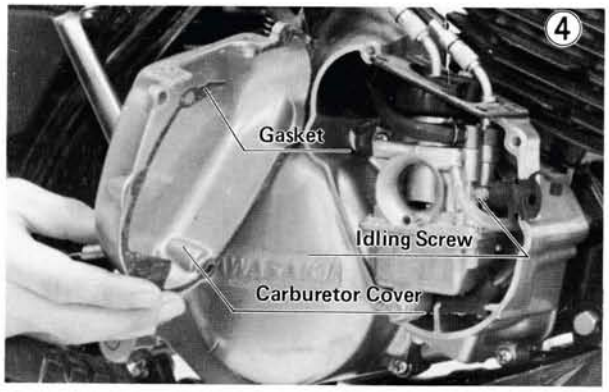
The carburetor cable forms one of the two lower branches of the throttle control cable assembly. It is adjusted so that, should the throttle valve be closed fully (not at idle but all the way down), all the play in the carburetor cable would be taken up.

The play that develops as the cable stretches will cause a delayed engine response, and should faulty adjustment cause the cable to pull the throttle valve out of its rest position, proper idling cannot be achieved. If the carburetor cable is out of adjustment, the oil and fuel/air mixture ratio will be incorrect, resulting in over or underlubrication. Adjust the carburetor cable in accordance with the Periodic Maintenance Chart (Pg. 152) to compensate for cable stretch and whenever the throttle does not respond properly.

- Remove the nuts (2) from the muffler exhaust collar.
- Remove the bolts (2) that connect the muffler to the frame and to the bracket at the rear shock absorber, and then remove the muffler and gasket.
- Check to see that the throttle grip has the proper amount of play (Pg. 9).
- Remove the bolts (4) from the carburetor rim, and slide the rim and carburetor rubber cap up the cables.

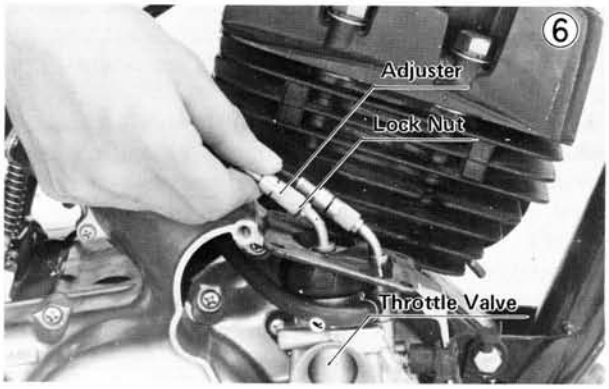


•Remove the carburetor cover and gasket, and pull out the cap from the hole to the idling screw.



•Back out the idling screw (throttle stop screw) 3 or 4 turns.

•Loosen the lock nut, and turn in the adjuster so that the throttle valve is at its lowest possible position.



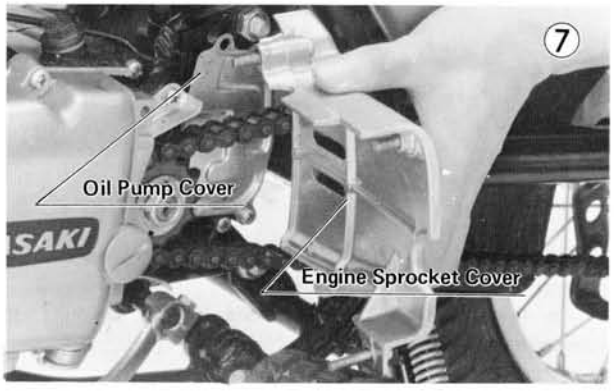
•Being careful not to turn the adjuster so far that the throttle valve rises out of its lowest position, turn the adjuster back out to eliminate the play so that the slightest tug on the outer cable will affect the throttle valve.
•Tighten the lock nut.
•Replace the carburetor cover and gasket, slide back the carburetor rubber cap and rim, and tighten the rim bolts.
•Fit the muffler and gasket back into the cylinder exhaust port, and loosely tighten the bolts that connect the muffler to the frame and to the bracket at the rear shock absorber.
•Replace the muffler exhaust collar nuts, tightening them together so that they tighten evenly to avoid an exhaust leak. Be sure that the spring side of the nuts face out.
•Tighten the muffler mounting bolts.
•Check to see that the throttle grip has the proper amount of play (Pg. 9).
•Check the oil pump cable adjustment (Pg. 10).
•Turn in the idling screw 3 or 4 turns, and start the engine.
•Replace the cap on the idling screw hole.
•Warm the engine up for 5 minutes, and then adjust the idling speed with the idling screw to the lowest stable speed obtainable, which will normally be 1,300 rpm.

NOTE: After this adjustment has been completed, a certain amount of play will exist between the carburetor inner cable and the throttle valve, the extent of which may be detected by taking out the adjuster clip and pulling on the outer cable. This play, which is the proper amount for a correct oil and fuel/air mixture ratio, must not be altered. To ensure the proper ratio, the oil pump alignment marks should be checked after the carburetor cable adjustment.

Oil Pump Cable

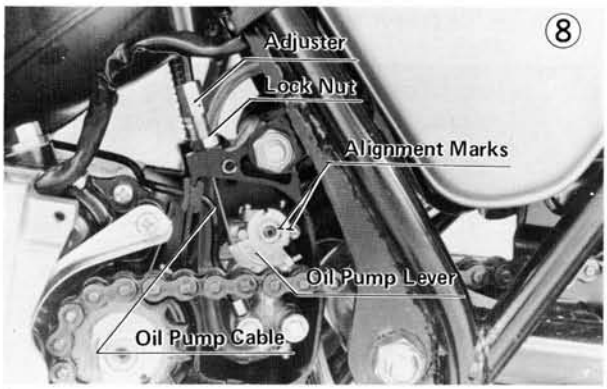
The oil pump cable forms one of the two lower branches of the throttle control cable assembly and connects to the oil pump lever. The cable must be kept adjusted so that the oil pump output which is dependent on throttle movement is minimal at zero throttle and increases at a predetermined throttle opening. This adjustment is correct when the lower mark on the oil pump lever lines up with the mark on the oil pump lever stopper at zero throttle (Fig. 8).

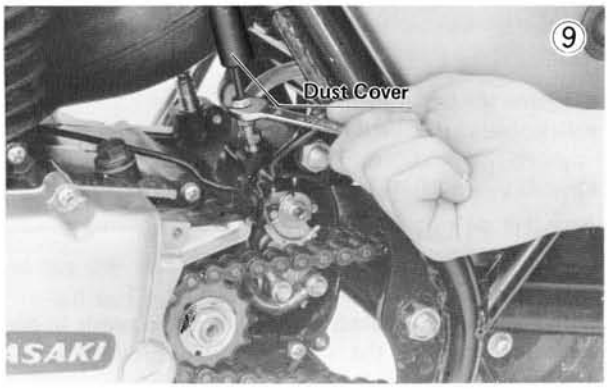
If adjustment is neglected or not carried out properly whenever necessary, the oil supply to the engine will become too low or too high, resulting in piston seizure from underlubrication or poor performance and spark plug trouble from overlubrication. The oil pump cable must be adjusted whenever the oil pump marks are found to be misaligned at zero throttle. In accordance with the Periodic Maintenance Chart (Pg. 152) and whenever white exhaust smoke is observed or an oil insufficiency is suspected, check the oil pump alignment marks and adjust the oil pump cable if necessary.
•Check that the throttle grip has the proper amount of play (Pg. 9).
•Remove the engine sprocket cover and oil pump cover.



●If the marks are not properly aligned, slide up the adjuster dust cover, loosen the adjuster lock nut, and turn the adjuster so that with the throttle grip fully closed the lower mark on the oil pump lever lines up with the mark on the lever stopper.

NOTE: The upper mark on the oil pump lever is designed to line up with the mark on the lever stopper when the throttle grip is fully open. It may be used to check whether or not the throttle grip is opening fully.





●Tighten the lock nut, and slide back the adjuster cover.
●Replace the oil pump cover and engine sprocket cover.
●Check that the throttle grip has the proper amount of play (Pg. 9).

CARBURETOR

Although some internal carburetor parts can be adjusted by replacement, repositioning, etc., these adjustments are covered in the Maintenance Section of this manual. The following procedure covers the idling adjustment, which is the adjustment necessary in periodic maintenance and whenever the idling setting has been disturbed.

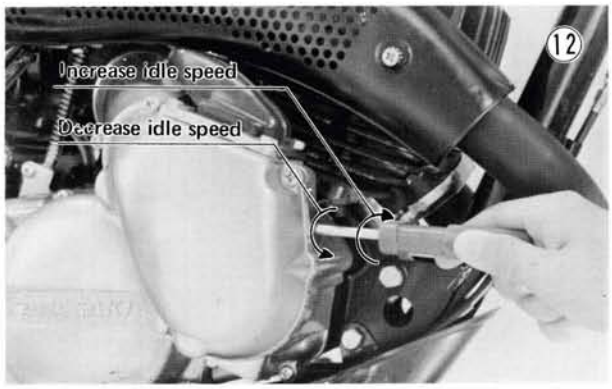
When the idling speed is too low, the engine may stall, and when the idling speed is too high, the fuel consumption becomes excessive, and a resulting lack of engine brake may make the motorcycle difficult to control.

For a proper fuel/air mixture at idling and low speed, it is important when adjusting the idling that the proper setting of the air screw is not neglected.

●Remove the carburetor rim bolts (2) which screw into the carburetor cover.

●Remove the carburetor cover.
●Turn in the air screw fully but not tightly, and then back it out 1½ turns (1 turn for Australian model).

●Replace the carburetor cover and tighten the rim bolts with 0.4~0.5 kg-m (35~43 in-lbs) of torque.
●Warm up the engine for about 5 minutes.
●Pull out the cap from the idling screw grommet.
●Adjust the idling speed with the idling screw to the lowest stable speed obtainable, which will normally be 1300 rpm. Turning the idling screw clockwise raises engine speed, while turning it counterclockwise lowers it.



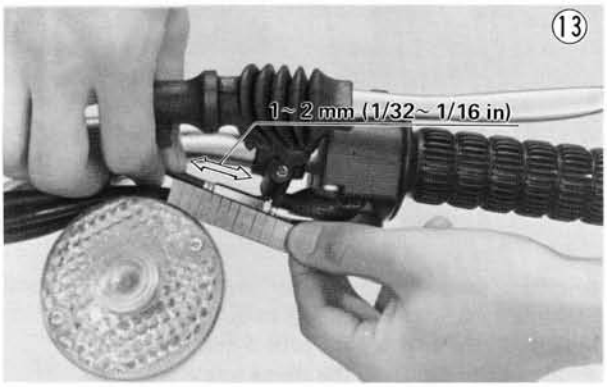
- Turn the throttle grip a few times to make sure that the idling speed is not changed after the grip is returned. Readjust if necessary.
- Turn the handlebar from side to side while idling the engine. If idling speed varies, the throttle control cable assembly may be poorly routed or the throttle grip cable play insufficient.
- Replace the idling screw grommet cap.

NOTE: The ignition timing must be correct for proper idling adjustment.

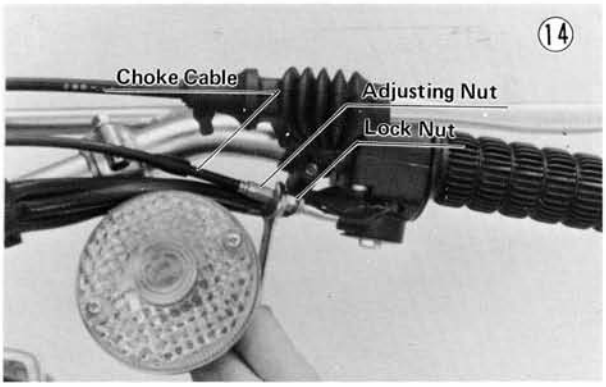
CHOKE CABLE

If the choke cable (more appropriately called a starter cable) is left too loose, the starter plunger may not open far enough when the choke lever is used. If the cable does not have enough play, the starter plunger may not fully close when the choke lever is returned, and the engine will always be running on too rich a mixture.

To determine the amount of cable play, first check to see that the choke lever is all the way returned to the left, and place a ruler alongside the upper end of the choke cable as shown in Fig. 13. Then pull out and push in the cable; the amount of cable travel is the amount of cable play. The proper amount of play is 1~2 mm (1/32~1/16 in). If there is too much or too little play, adjust the choke cable.



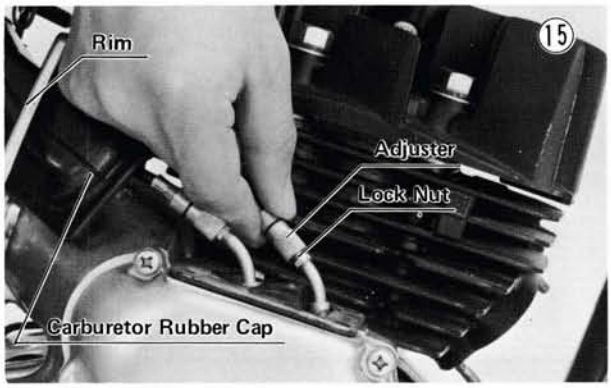
- Loosen the lock nut at the upper end of the choke cable, and turn the adjusting nut until the cable has the proper amount of play.



- Tighten the lock nut.

If the proper amount of play cannot be obtained with the adjusting nut at the upper end of the cable, carry out the following steps:

- Remove the muffler (Pg. 30).
- Remove the bolts (4) from the carburetor rim, and slide the rim and carburetor rubber cap up the cable to gain access to the adjuster at the lower end of the choke cable.
- Loosen the lock nut, and turn the adjuster until the cable has the proper amount of play.

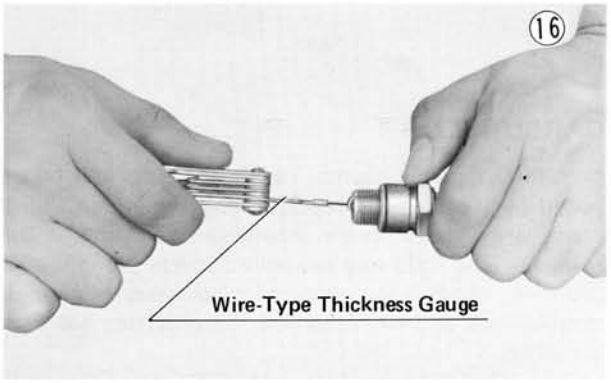


- Tighten the lock nut.
- Slide back the carburetor rubber cap and rim, and tighten the rim bolts.
- Install the muffler (Pg. 30).

SPARK PLUG

Spark plug electrode wear will widen the gap and cause missing and difficulty in starting. Too narrow a gap as a result of maladjustment will also result in poor performance since the small gap will produce only a weak spark.

- Remove the spark plug using a spark plug wrench.
- Clean the spark plug preferably in a sand-blasting device, and then clean off any abrasive particles. The plug may also be cleaned using a high flash-point solvent and a wire brush or other suitable tool.
- Measure the gap with a wire-type thickness gauge. The gap should be 0.6~0.7 mm (0.024~0.028 in); if it is not, bend the outer electrode with a suitable tool to obtain the correct gap.



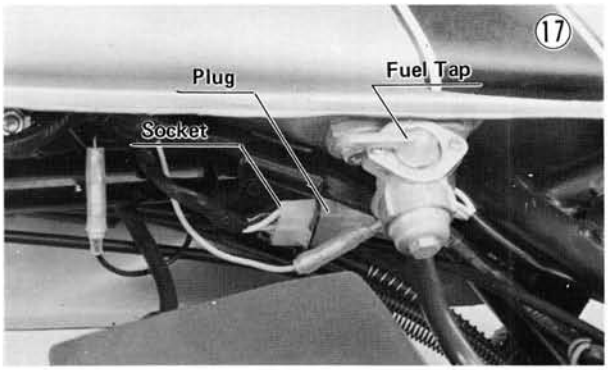
- Tighten the spark plug into the cylinder head to 2.5~3.0 kg-m (18.0~22 ft-lbs) of torque.

IGNITION TIMING

Incorrect ignition timing can cause poor performance, knocking, overheating, and serious engine damage. Periodic adjustment will be necessary to compensate for wear of parts, and the ignition timing must be checked whenever ignition related parts have been disassembled or replaced.

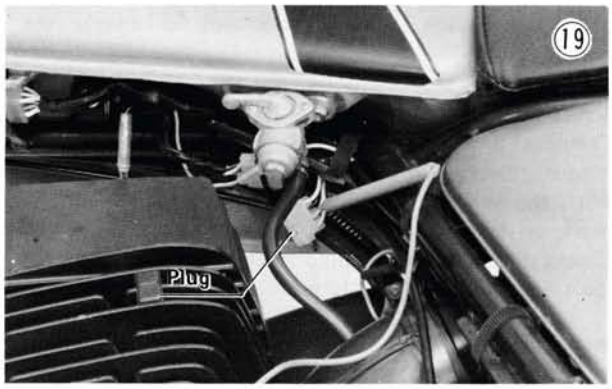
Correct ignition timing is achieved by adjusting through the inspection window of the magneto flywheel the position of the contact breaker base so that the points are just beginning to open when the timing mark on the outer circumference of the flywheel aligns with the timing projection on the crankcase, or when the piston is positioned 2.52 mm (0.0992 in) BTDC (before top dead center) by the use of a dial gauge. When the timing mark is aligned with the timing projection, the piston is positioned 2.52 ± 0.22 mm (0.0992 ± 0.009 in) BTDC, by which the ignition can be set for good performance. However, superior performance is generally achieved by having ignition take place as close as possible to 2.52 mm BTDC. When precise ignition timing is desired, a dial gauge is used in place of the timing mark and projection to set the position of the piston. Once the timing has been adjusted, it may be checked for accuracy by the use of a strobe light. There is no adjustment for maximum point gap.

- Remove the engine sprocket cover and left engine cover.
- Undo the white socket and plug from where they connect near the fuel tap.

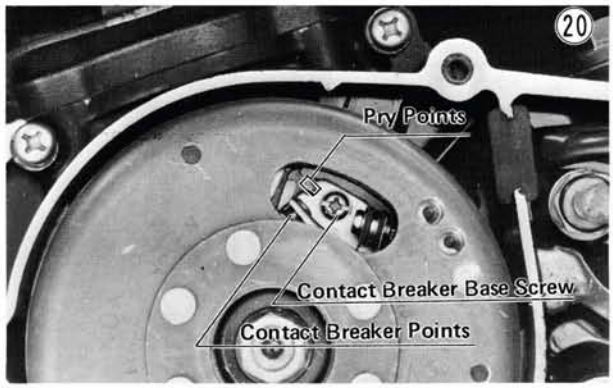


- Turn the magneto flywheel until the timing on the flywheel outer circumference aligns with the projection on the crankcase. (There are two lines on the flywheel of '74 and '75 models. The left line is the timing mark. The line to the right indicates where the woodruff key groove is located on the flywheel hub to facilitate flywheel installation.)

- Connect an ohmmeter set to the Rx1 range across the contact breaker points by securing one lead to chasis ground (such as the crankcase) and inserting the other lead into the hole where the black magneto output lead connects to the white plug. Be sure that the ohmmeter leads are connected with firm electrical contact.



- Loosen the contact breaker base screw just enough to allow the base to move.

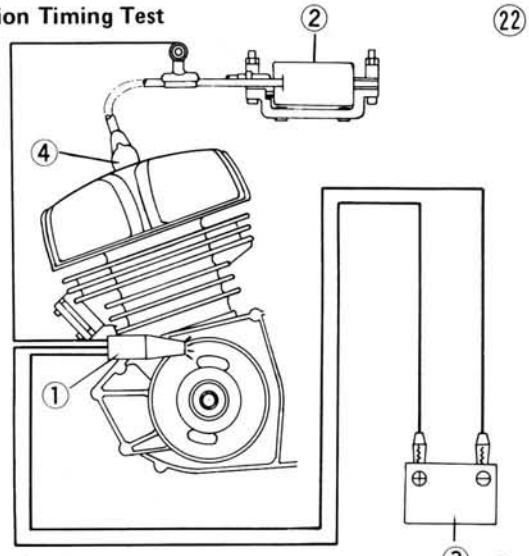


- Use a screwdriver on the pry points to adjust the position of the contact breaker base until the contact breaker points are just at the point of opening. The ohmmeter needle starts to rise when the points just begin to open. Note that total needle travel as the points open is only about 3Ω.

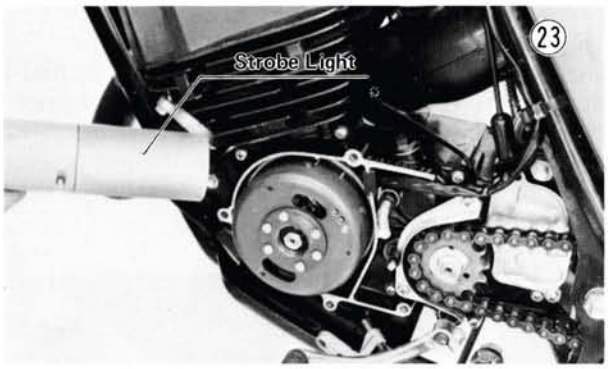
•Once the base seems properly positioned, tighten the base screw, rotate the flywheel a little clockwise, and then slowly rotate it counterclockwise. When the needle starts to rise, the timing mark and projection should be aligned. If they are not, readjust and recheck until the correct contact breaker base position is reached.
•Disconnect the ohmmeter, and reconnect the white plug and socket, being careful not to reverse the connection.

To check to see whether or not the ignition timing is correctly set, a strobe light may be used.
•Connect the light in the manner prescribed by the manufacturer. One example is shown in Fig. 22 .
•With the engine idling, direct the light at the timing mark on the crankcase. If the timing mark and the timing projection are aligned when the light flashes, the ignition timing is correctly set.

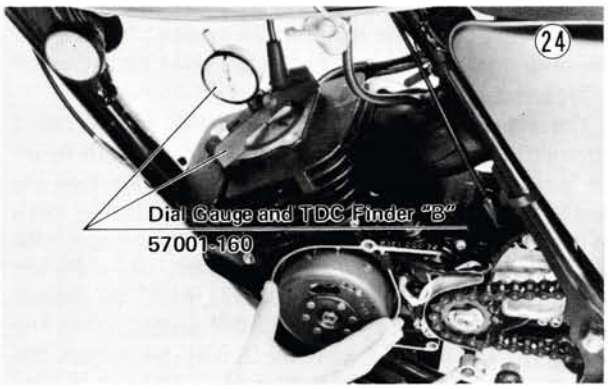
Ignition Timing Test (22)



1. Strobe Light
2. Ignition Coil
3. Battery
4. Spark Plug Cap



For even better accuracy, a dial gauge can be used to set the position of the piston. Instead of aligning the timing mark and projection, the following steps can be substituted:
•Remove the cylinder head (Pg. 31). Muffler removal is not necessary.
•Rotate the magneto flywheel counterclockwise until the position of the piston is close to the top.
•Using TDC finder "B" (special tool), mount a dial gauge on the cylinder, rotate the flywheel to set the piston at exact TDC, and set the dial to zero.



•Rotate the flywheel clockwise until the dial gauge reads about 3.0 mm (0.12 in) and then counterclockwise until the dial gauge reads 2.52 mm (0.0992 in).

At this point the piston is properly positioned such that, while using an ohmmeter (or some other suitable device), the contact breaker base can be adjusted to set the timing. When replacing the cylinder head, be sure that the gasket is properly fitted and that the nuts are tightened in a cross pattern with 2.2 kg-m (16 ft-lbs) of torque (Pg. 156).

NOTE: When setting the ignition timing by the use of a dial gauge to determine piston position, the flywheel timing mark is not used to check the timing. The dial gauge reading is referred to throughout the entire adjustment instead of the timing mark and projection. Before checking with a strobe light, first make a new timing mark by marking the flywheel just under the projection once the piston has been set at 2.52 mm (0.0992 in) BTDC.

CLUTCH

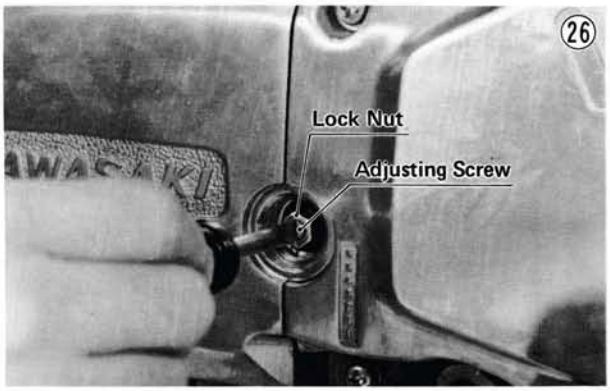
Stretching of the clutch cable causes the clutch lever to develop excessive play. Too much play will prevent the lever from fully disengaging the clutch and will result in shifting difficulty and possible clutch or transmission damage. Most of the play must be adjusted out, but a small amount has to be left so that the clutch will engage fully without slipping.

Besides cable stretch, clutch plate wear also causes the clutch to go out of adjustment. Although the clutch lever is not pulled in, the push rod will begin to oppose clutch spring pressure as this wear progresses. For proper clutch adjustment, the clutch adjusting screw must be screwed out to eliminate the push rod opposition to spring pressure while the clutch is engaged.

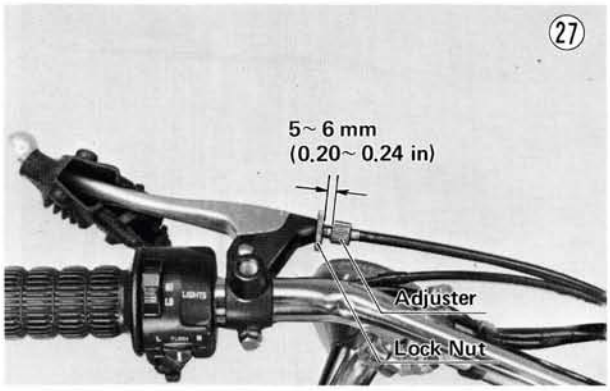
Adjust the clutch in accordance with the Periodic Maintenance Chart (Pg. 152) and whenever the clutch does not function properly. If satisfactory clutch operation is not achieved by clutch adjustment, inspect the clutch for wear and damage (Pg. 104).

The adjustment procedure which follows compensates for both cable stretch and plate wear.

- Unscrew and remove the clutch adjusting hole cap and gasket.
- Loosen the lock nut. If the clutch adjusting screw does not turn loosely already, back it out until it does.

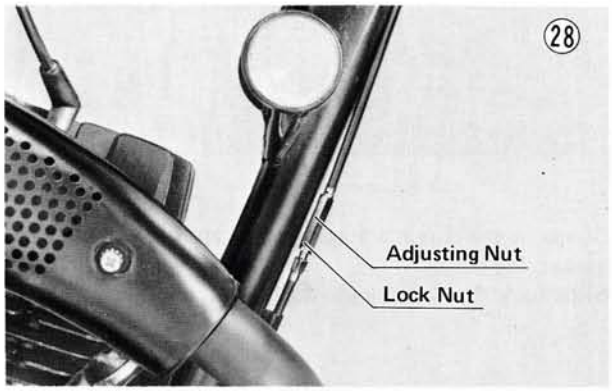


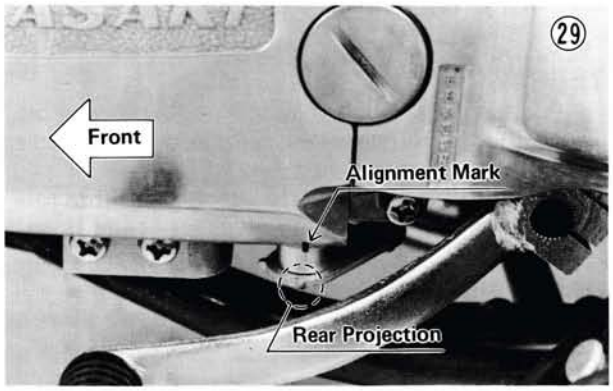
- Slide the clutch lever dust cover out of place.
- Loosen the lock nut just enough so that the adjuster will turn freely, and then turn the adjuster to make a 5~6 mm (0.20~0.24 in) gap between the adjuster and lock nut.



- Loosen the lock nut at the center of the clutch cable, turn the adjusting nut at the center of the clutch cable so that the rear projection on the clutch release lever is just under the mark on the magneto cover, and then tighten the lock nut.

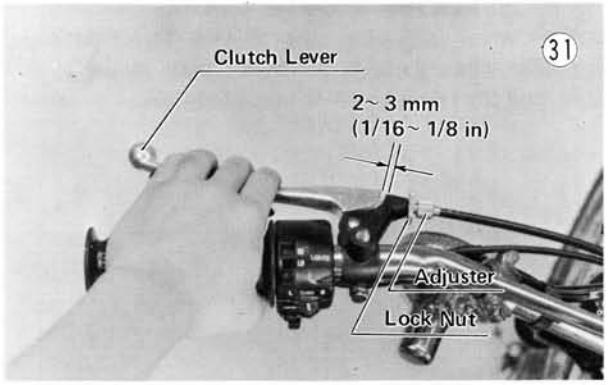
NOTE: When adjusting the release lever position, especially when there is plenty of play in the clutch cable, pull the release lever towards the rear.





- Turn the clutch adjusting screw in to just where a resistance is felt, and then tighten the locknut.

●Turn the adjuster at the clutch lever so that the clutch lever will have 2 ~ 3 mm ($^1/_{16} \sim ^1/_8$ in) of play, and tighten the lock nut.



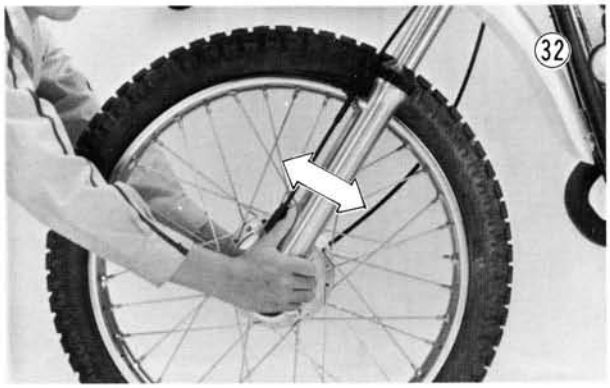
●Screw in the clutch adjusting hole cap together with its gasket.
●Slide back the clutch lever dust cover.

STEERING

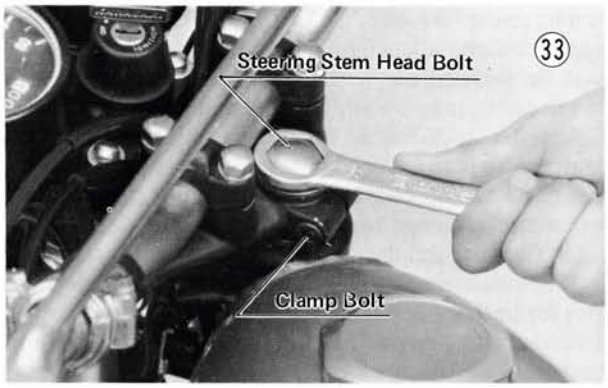
For safety, the steering should always be kept adjusted so that the handlebar will turn freely but not have excessive play.

If the steering is too tight, it will be difficult to turn the handlebar quickly, the motorcycle may pull to one side, and the steering stem bearings may become damaged. If the steering is too loose, the handlebar will vibrate, and the motorcycle will be unstable and difficult to steer in a straight line.

To check the steering adjustment, first place a stand or block under the engine so that the front wheel is raised off the ground. Push the handlebar lightly to either side; if it continues moving under its own momentum, the steering is not too tight. Squatting in front of the motorcycle, grasp the lower ends of the front fork at the axle, and push and pull the front end back and forth; if no play is felt, the steering is not too loose.

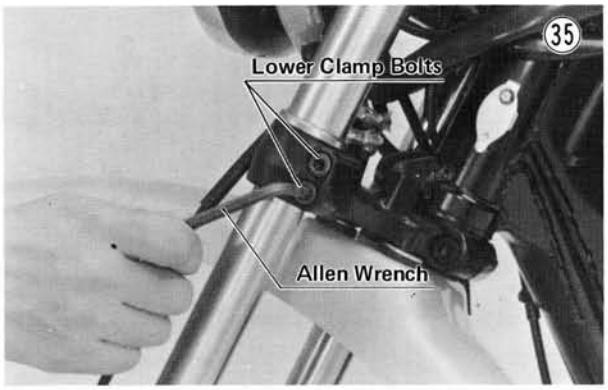


●Loosen the steering stem head bolt and the clamp bolt.



●Using the stem nut wrench, tighten the steering stem lock nut to 1.8 ~ 2.2 kg-m (13 ~ 16 ft-lbs) of torque.

●Tighten down the steering stem head bolt to 3.0 kg-m (22 ft-lbs) of torque.
●Tighten the stem head clamp bolt to 1.6 ~ 2.2 kg-m (11.5 ~ 16 ft-lbs) of torque.
●Loosen the lower clamp bolts (4) on the left and right shock absorbers to let the tubes reseat themselves, and then retighten the bolts to 1.6 ~ 2.2 kg-m (11.5 ~ 16 ft-lbs) of torque.



●Check the steering again, and readjust if necessary.

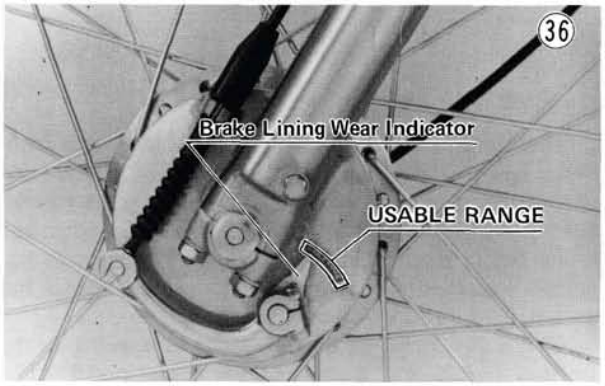
BRAKES

Brake lining wear, drum wear, and cable stretch cause the brakes to go out of adjustment, increasing lever and pedal play and decreasing braking effectiveness. Brake adjustment to compensate for this consists of correcting the cam lever angle and adjusting the front brake lever and rear brake pedal travel.

Once the brakes have been adjusted, spin or turn the wheels to check for drag. If any drag is heard or felt, disassemble the brake (Pgs. 65 and 68), and inspect for wear or damage (Pg. 123). Also, if the brake lever or pedal does not return to its rest position quickly upon release, inspect the brake for wear or damage.

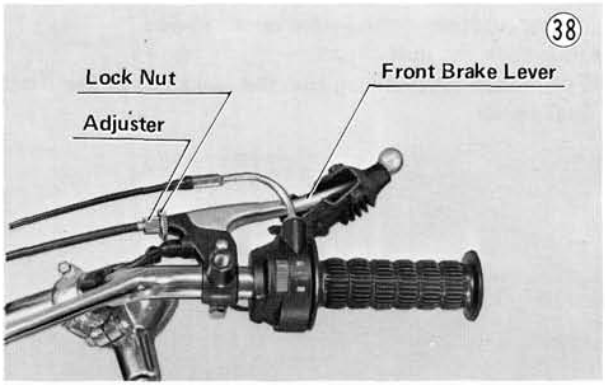
On the outside of both the front and rear brake panels there is a brake lining wear indicator. Whenever the indicator has gone past USABLE RANGE, the brake shoes must be immediately replaced and the other brake parts examined. Adjustment alone cannot compensate for the wear of a brake worn past USABLE RANGE.

CAUTION: Since a cam lever angle greater than 90° reduces braking effectiveness, this adjustment should not be neglected. When remounting the cam, be sure that the position of the indicator on the serrated shaft is not altered. The change in cam lever angle is caused by wear of internal brake parts. Whenever the cam lever angle is adjusted, also check for drag and proper lever or pedal operation, taking particular note of the brake lining wear indicator position. In case of doubt as to braking effectiveness, disassemble and inspect all internal brake parts. Worn parts could cause the brake to lock or fail.



Front Brake Lever

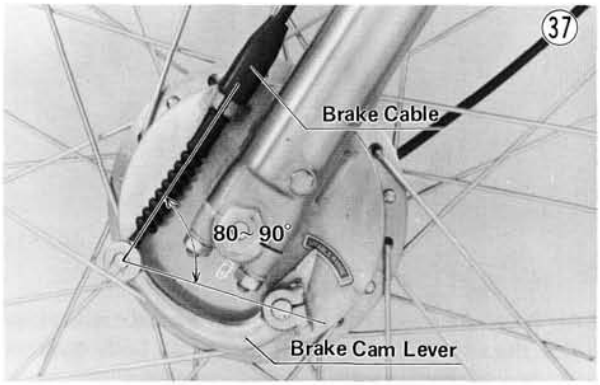
- Slide the front brake lever dust cover out of place.
- Loosen the lock nut at the front brake lever, screw the adjuster fully in, and tighten the lock nut.

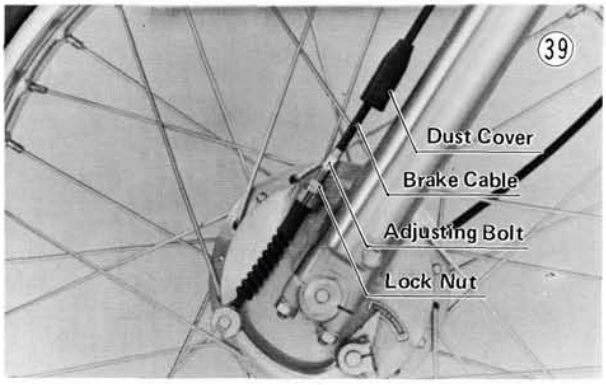


Front and Rear Brake Cam Lever Angle

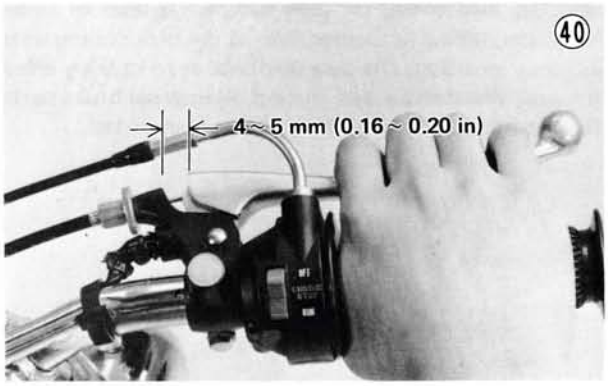
- When the brake is fully applied, the brake cam lever should come to an 80~90° angle with the threaded extension of the brake cable. If it does not, loosen the cable adjusting nut, remount the cam lever at a new position on the shaft for the proper angle, and then adjust cable play.

- Slide up the dust cover, and loosen the lock nut at the lower end of the brake cable.





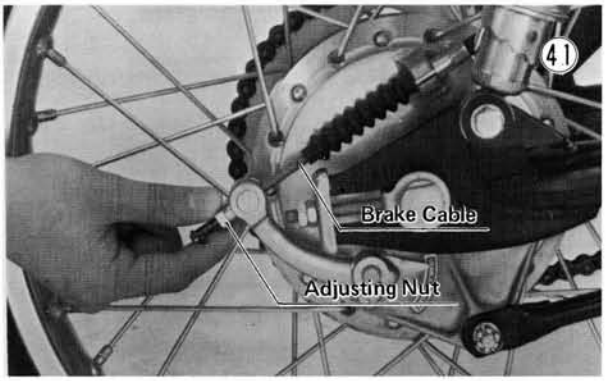
•Turn the adjusting bolt on the lower end of the front brake cable so that the brake lever has 4~5 mm (0.16 ~0.20 in) of play.

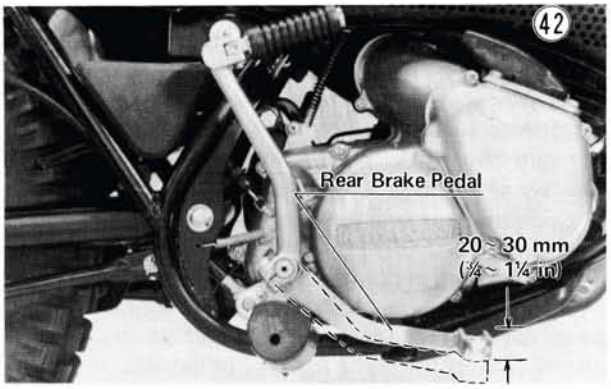


•If sufficient adjustment cannot be made with the adjusting bolt, complete the adjustment with the adjuster at the brake lever, and then tighten all lock nuts.
•Check for brake drag.
•Operate the lever a few times to see that it returns to its rest position immediately upon release.
•Slide back the dust covers.
•For minor corrections, use the adjuster at the front brake lever.

Rear Brake Pedal

•Turn the adjusting nut on the end of the threaded extension of the rear brake cable so that the brake pedal has 20~30 mm (¾~1¼ in) of travel from the rest position to the fully applied position.





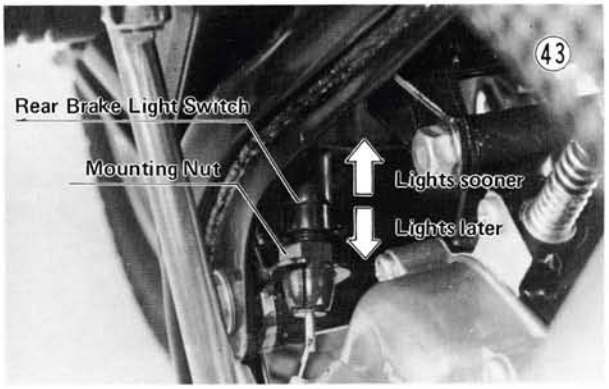
•Check for brake drag.
•Operate the pedal a few times to see that it returns to its rest position immediately upon release.
•Check the rear brake light switch adjustment.

BRAKE LIGHT SWITCH

The front brake light switch, mounted on the front brake lever, is operated by simple electrical contact and should not need adjustment. However, the rear brake light switch, activated by a wire spring attached to the brake pedal, may require adjustment if the spring has gotten stretched or if the spring or brake pedal has gotten bent or warped.

Check the operation of the switch by turning on the ignition switch and depressing the brake pedal. The brake light should go on after 15 mm ($^5/_8$ in) of pedal travel or shortly before the brake pedal reaches the fully applied position.

•Turn the switch adjusting nut up or down so that the brake light will go on after the correct amount of brake pedal travel. A higher switch position will make the light go on after less travel.

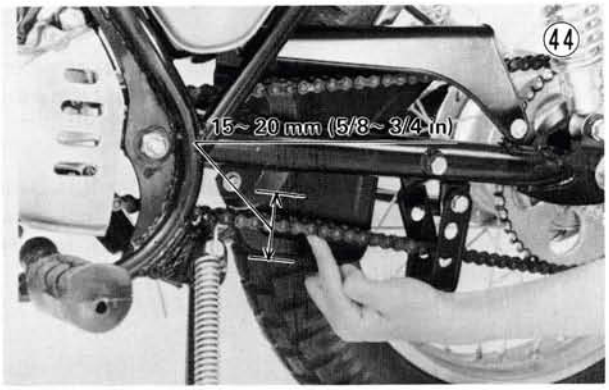


CAUTION: To avoid damaging the electrical connections inside the switch, be sure that the switch body does not turn during adjustment.

DRIVE CHAIN

Chain and sprocket wear causes the chain to lengthen, which results in power loss, accelerated chain and sprocket wear, and increased noise. A lengthened chain which is not adjusted properly may possibly be thrown off the sprockets or break. A chain that has been adjusted too tight will wear excessively and possibly break.

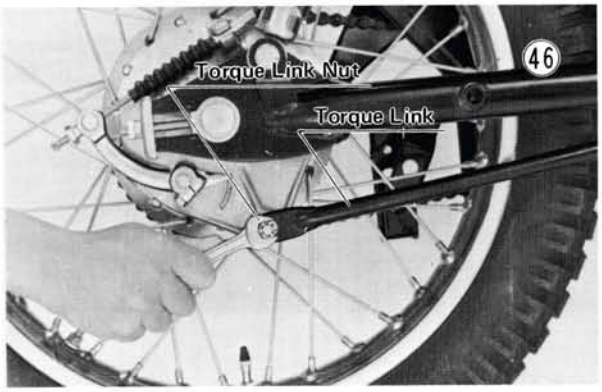
First turn the rear wheel to find the part of the chain that is tightest, and make the adjustment using this part. With the motorcycle on its side stand, the chain should have about 15 ~ 20 mm ($^5/_8$ ~ $^3/_4$ in) of vertical movement midway between the sprockets. If the slack exceeds 25 mm (1 in), adjust the chain.



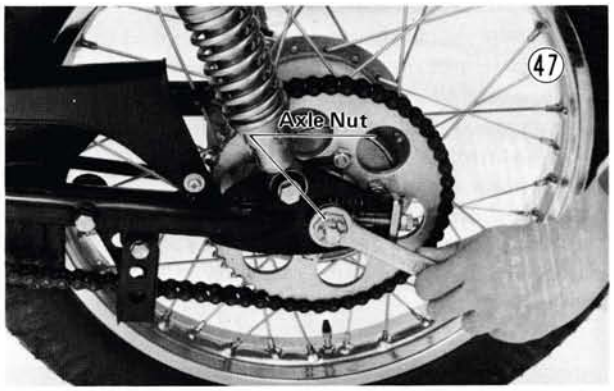
Chain Slack

CAUTION: A chain worn past the service limit (Pg.125) should be replaced. Such wear cannot be adequately compensated by adjustment.

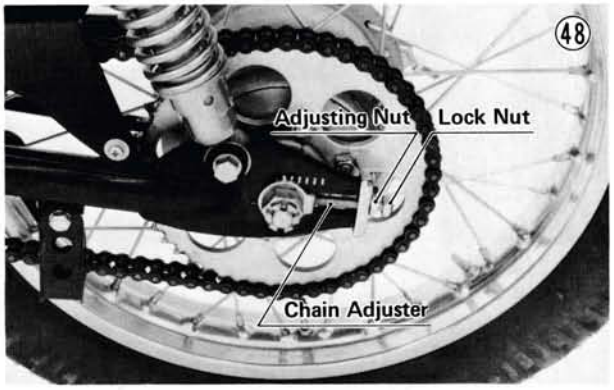
- Remove the cotter pin, and loosen the torque link rear nut.



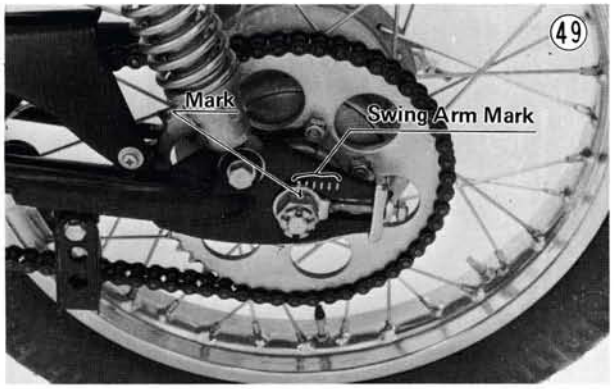
- Remove the cotter pin, and loosen the axle nut.



- Loosen the lock nut on both chain adjusters.



- If the chain is too tight, back out the adjusting nut on both chain adjusters, and then kick the wheel forward until the chain becomes overly loose.
- Turn in the right and left chain adjusting nuts evenly until the chain has the correct amount of slack. To keep the chain and the wheel aligned, the mark on the left chain adjuster must come to the same swing arm mark that the right chain adjuster mark comes to.

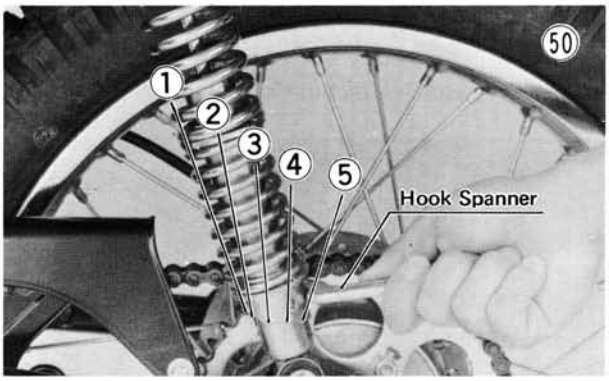


- Tighten both adjuster lock nuts, and then tighten the axle nut with 8.5~11.5 kg-m (61~83 ft-lbs) of torque.
- Rotate the wheel, measure the amount of slack, and readjust if necessary.
- Insert a new cotter pin through the axle nut and axle.
- Tighten the torque link rear nut with 2.0~2.2 kg-m (14.5~16 ft-lbs) of torque, and insert a new cotter pin.

REAR SHOCK ABSORBERS

The rear shock absorbers can be adjusted to one of 5 positions to suit riding conditions. They can be left soft for average riding but should be adjusted slightly harder for high speed riding or for riding on bad roads.

Adjustment is made by turning the adjusting sleeve with a hook spanner. The higher the adjusting sleeve is positioned, the harder the shock absorption. Be sure to turn both left and right shock absorbers to the same position in order to maintain stability.

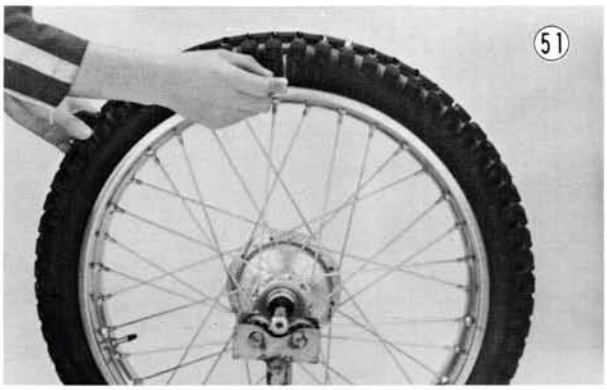


WHEEL BALANCE

To improve stability and decrease vibration at high speed, the front and rear wheels must be kept balanced.

Check and balance each wheel as follows:

- Remove the wheel (Pg. 64 or 67).
- Check that all the spokes are tightened evenly.
- Suspend the wheel so that it can be spun freely.



- Spin the wheel lightly several times, and see if it stops of its own accord in various positions, indicating that it is correctly balanced.
- If one part of the wheel always stops at the bottom, mark the side of the tire at the top, and attach a balance weight loosely to the spoke closest to the mark.

- Repeat the previous two steps as many times as necessary to correctly balance the wheel, and then clamp the weights on firmly using pliers.
- Remount the wheel onto the motorcycle.

NOTE: Balance weights are available from Kawasaki Dealers in 10, 20, and 30 gram ($^1/_3$, $^2/_3$, and 1 oz) sizes. An imbalance of less than 10 grams will not usually affect running stability.

HEADLIGHT

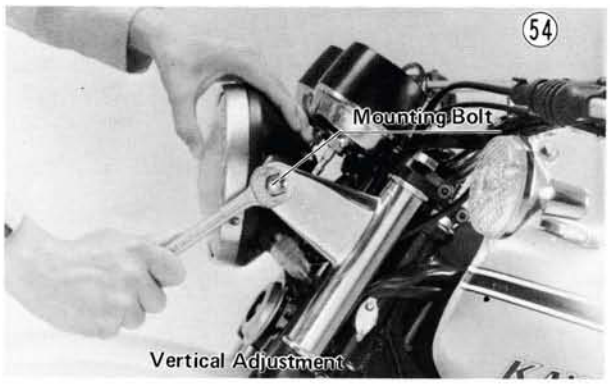
The headlight beam is adjustable both horizontally and vertically. If not properly adjusted horizontally, the beam will point to one side rather than straight ahead. If adjusted too low vertically, neither low nor high beam will illuminate the road far enough ahead. If adjusted too high vertically, high beam will fail to illuminate the road close ahead, and low beam will blind oncoming drivers.

Horizontal Adjustment:

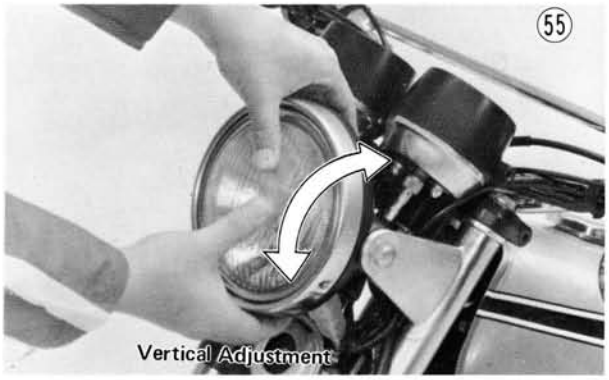
- Turn in or out the small screw on the headlight rim until the beam points straight ahead.

Vertical Adjustment:

- Loosen the headlight housing mounting bolts just enough so that the headlight can be moved.



●Move the headlight up or down by hand to where the vertical aim is correct.



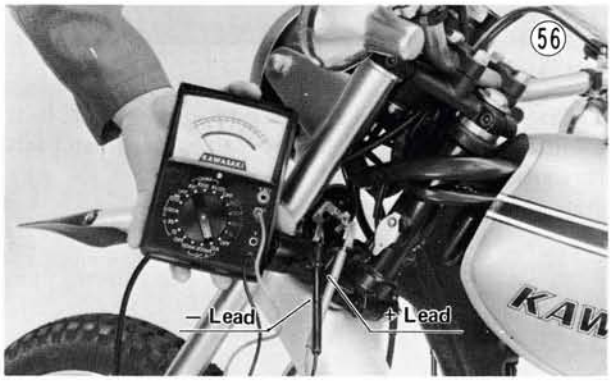
●Tighten the headlight housing mounting bolts.

HORN

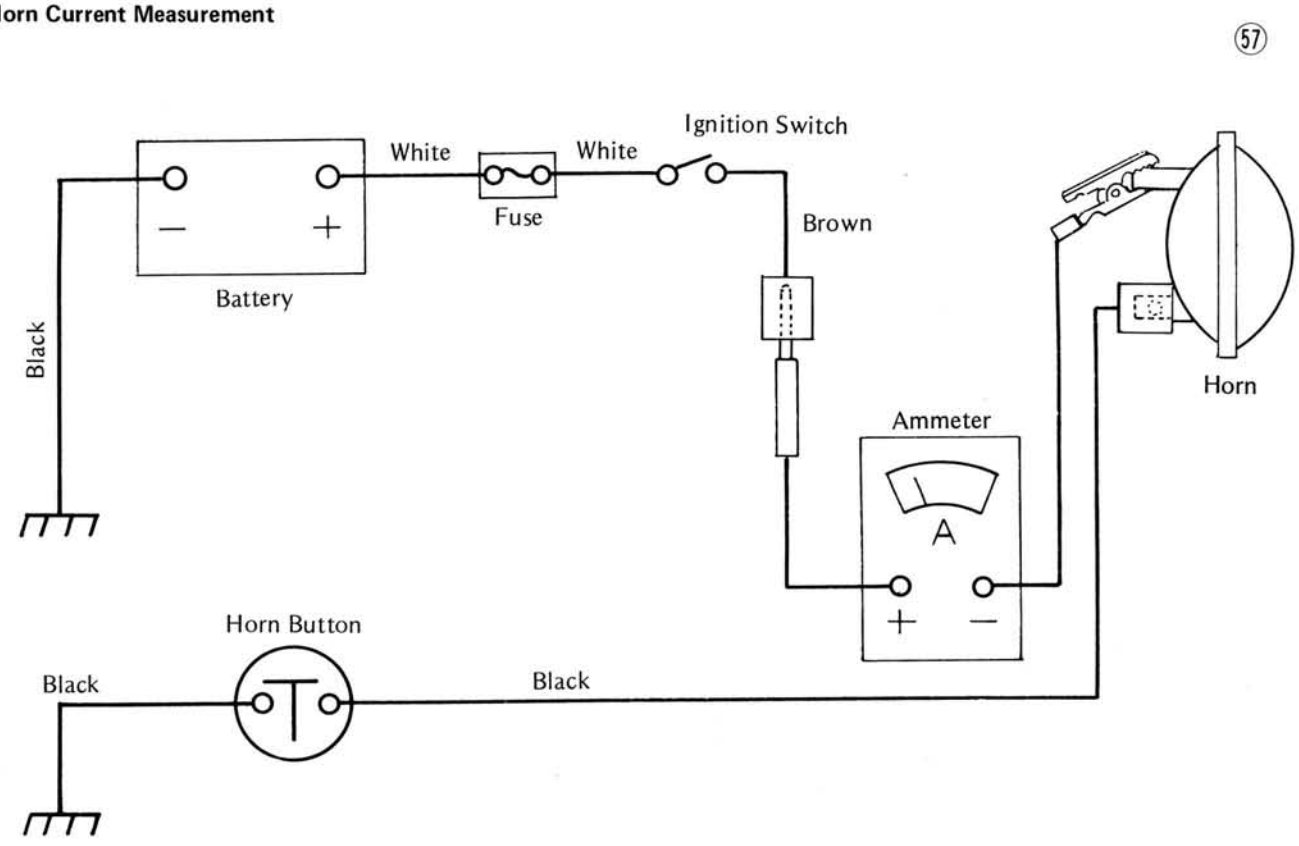
The horn contacts wear down after long use and will need to be adjusted from time to time. Turning out the adjusting screw compensates for contact wear. If satisfactory horn performance cannot be obtained by this adjustment when the rest of the electrical system is functioning properly, the horn must be replaced. It cannot be disassembled.

CAUTION: Do not turn the adjusting screw out too far since doing so will damage the horn spring and increase the horn current, possibly burning out the horn coil.

●Disconnect the brown lead from the horn, and connect an ammeter into the circuit in series. The + ammeter lead goes to the brown lead, and the – ammeter lead goes to the horn terminal.



Horn Current Measurement



- Turn on the ignition key, and keep the horn button pressed while turning the horn adjusting screw. Adjust for a healthy horn sound while keeping the current as close as possible to 1.5 amperes. In no event should the current be allowed to exceed 2.2 amperes since at higher amperage the horn life is seriously shortened.

NOTE: The horn will not sound properly if it is mounted incorrectly or if any cables or other parts are touching it.

Disassembly

Installation:

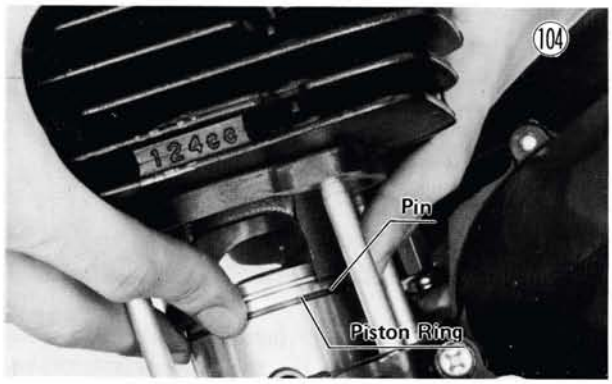
- Replace the cylinder base gasket with a new one.
- Daub a little 2 stroke oil on the piston rings and the inside surface of the cylinder.
- Set the piston at BDC, and fit the base of the cylinder over the rings, pressing in on opposite sides of the rings as necessary. Be certain that the rings do not slip out of their proper position. The pin in each piston groove must be between the ends of its piston ring.



●Replace the cylinder head gasket on the cylinder so that the gasket holes perfectly match the cylinder bore and stud holes. Only one of the four possible positions is correct. The top side (the side with the beveled inner perimeter) should face up.

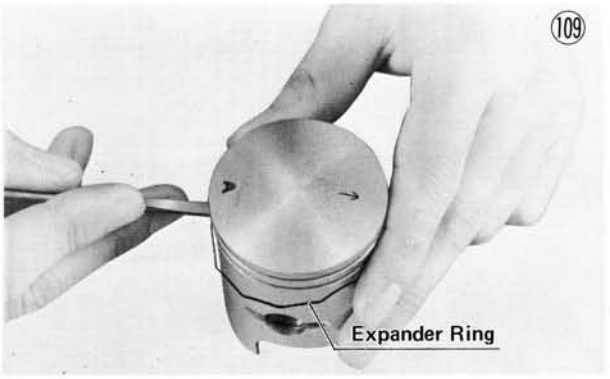
●Remove the expander ring.

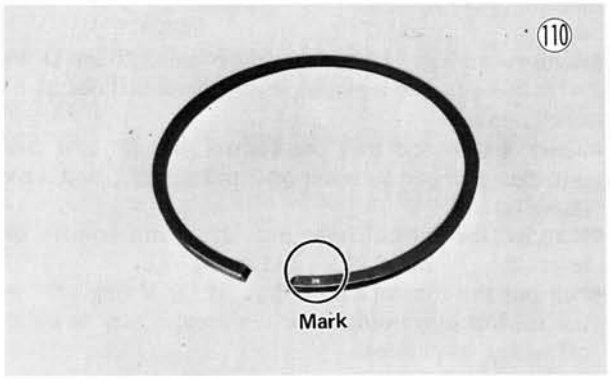


Installation Notes:

1. Apply oil to the connecting rod needle bearing before inserting it.
2. If the piston is replaced with a new one, piston to cylinder clearance changes (Pg. 99). Also, when a new piston or piston pin is used, check that the piston to pin clearance is 0.0024~0.0084 mm (0.00009 ~0.00033 in).

To the Dealer: When possible, match parts from stock so that a marked pin is assembled with an "A" piston and an unmarked pin with a "B" piston.

3. Install the piston rings so that the correct side (marked "N") faces up (Fig. 110).



4. When replacing the piston rings by hand, first fit one end of the piston ring against the pin in the piston groove, spread the ring opening with the other hand, and then slip the ring into the groove.
5. The arrow on the top of the piston must point towards the front.

6. Apply a little oil to the piston pin before inserting it.
7. Use a new piston pin snap ring in place of every one that is removed since removal weakens and deforms it. After installation, turn the snap ring so that its opening does not coincide with either groove in the side of the piston.

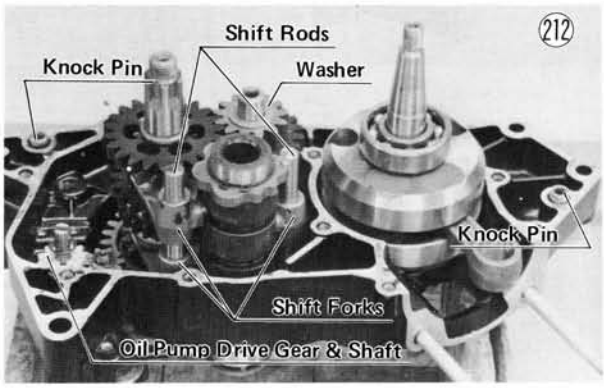
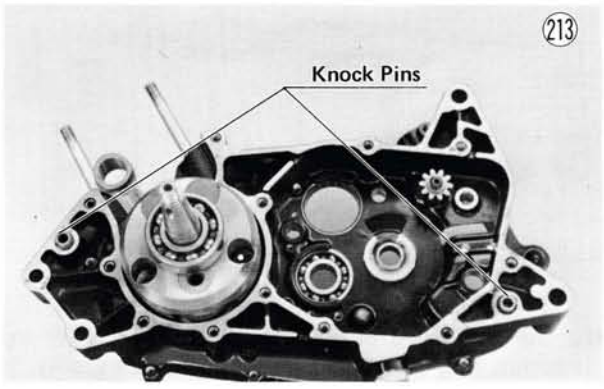
- Once the crankcase is split, remove the crankcase splitting tool, and lift off the left crankcase half. Remove the shift rods (2), shift forks (3), shift drum, and output and drive shaft assemblies. A washer on the left side of the drive shaft, a washer where the oil pump drive gear fits in the right crankcase half, the crankcase knock pins (2), and the oil pump drive gear & shaft may fall loose. Remove and place the washers, knock pins (if loose), and the oil pump drive gear & shaft to one side.



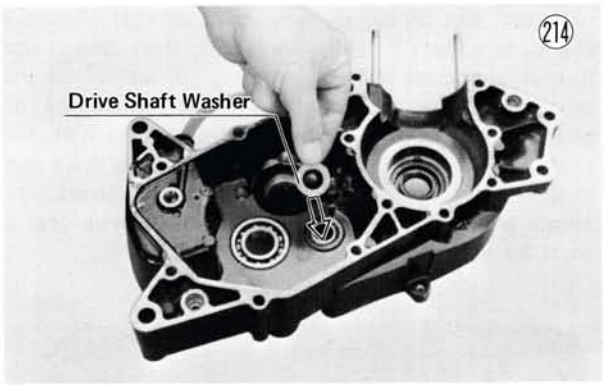
- Pull out the output shaft sleeve and O ring from the left crankcase half.

Installation:

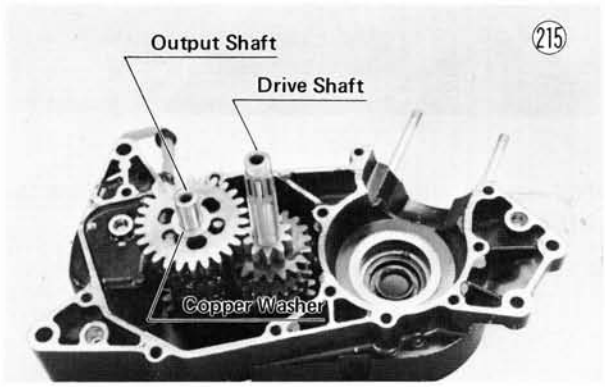
- Clean out the crankcase, and clean off any grime on any of the transmission and crankshaft parts with kerosene.
- **Check to see that both crankcase halves are fully assembled (Pgs. 63 and 64).**
- Replace the crankcase knock pins (2) if they were removed.



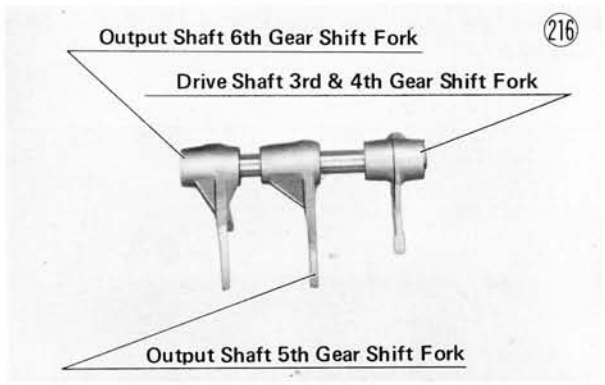
●Place the drive shaft washer onto its place in the left crankcase half.



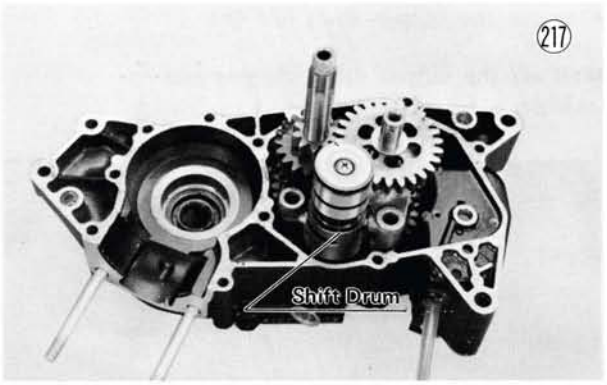
●Mesh the output shaft gears with those on the drive shaft, and fit both assemblies into the left crankcase half. Check to see that the copper washer is on the upper end of the output shaft assembly.



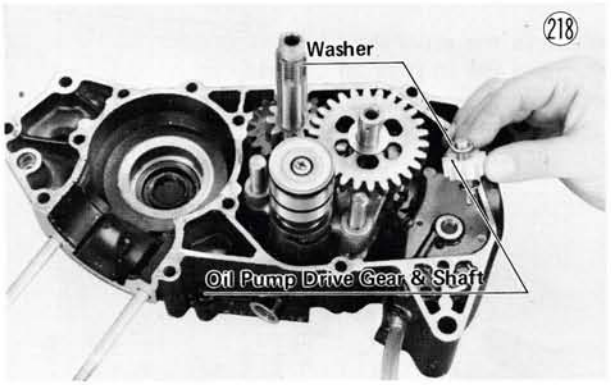
●Fit each shift fork into the groove on its gear. Drive shaft 3rd & 4th gear shift fork fingers are centrally located on the fork hub. Output shaft 5th gear shift fork fingers are non-centrally located on the fork hub to one extreme side. Output shaft 6th gear shift fork fingers are non-centrally located on the fork hub slightly off center.



●Fit the shift drum into the left crankcase half fitting each shift fork guide pin into its shift drum groove.



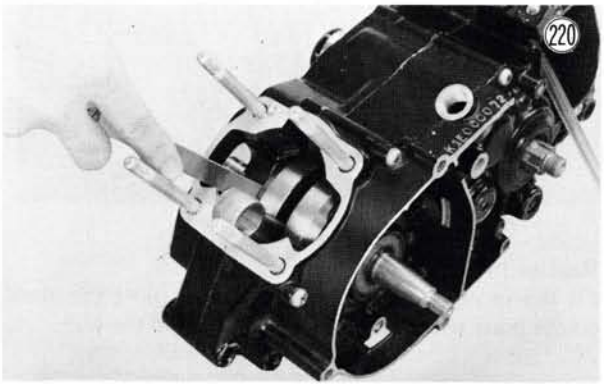
●Insert the shift rods. The long shift rod is for the output shaft side.
●Fit the washer and the oil pump drive gear & shaft back into place in the left crankcase half.



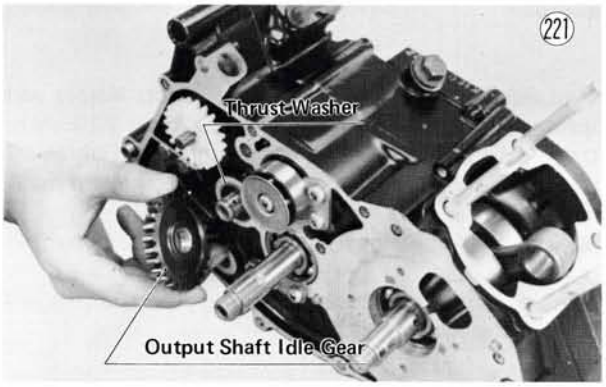
●Replace the oil pump gear.
●Apply liquid gasket to the mating surface of the left crankcase half, and fit the crankcase halves together using a press. As the halves come together, rotate the tachometer gear shaft so that the oil pump drive gear will mesh with tachometer drive gear #1. While using the press, be sure that the surface on the right crankcase half where the rotary disc rubs does not get scratched.

●After the crankcase halves are fitted together, screw in the crankcase screws (12). Tighten them with an impact driver.

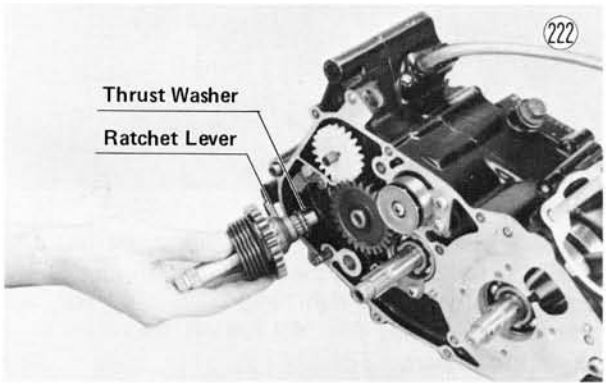
- Measure with a thickness gauge the clearance between each flywheel and the crankcase. If the crankshaft is not centrally located, tap the appropriate end of the crankshaft with a plastic, soft brass, or lead hammer to reposition it.



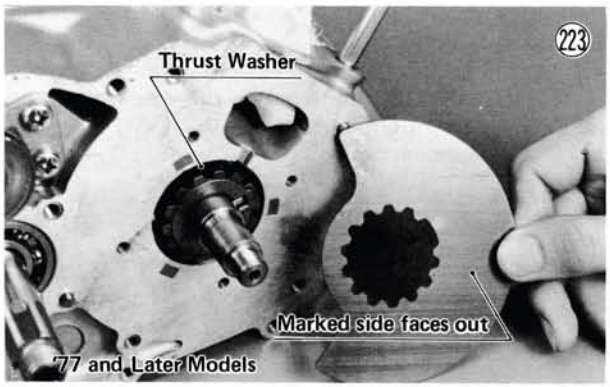
- Check to see that the crankshaft, drive shaft, and output shaft all turn freely.
- Replace the shift drum stopper. The shift drum stopper is thicker than the drive shaft bearing stopper.
- Replace the shift drum positioning pin, spring, gasket, and tighten the bolt with 1.5 kg-m (11 ft-lbs) of torque.
- Replace the drive shaft bearing stopper.
- Replace the thrust washer, output shaft idle gear, thrust washer, and circlip. The side of the hub that protrudes the most faces in.



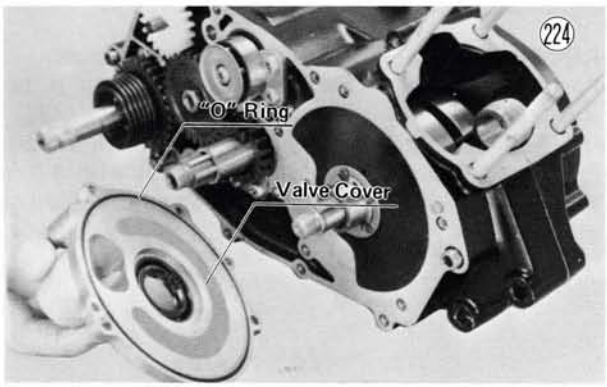
- Put the thrust washer on the crankcase end of the kick shaft, and then push the kickstarter back into place with the ratchet lever to the left.



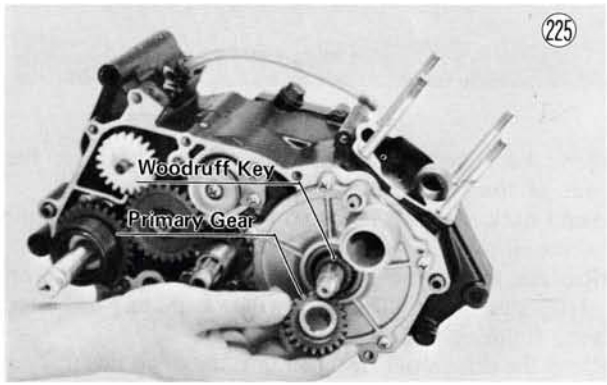
- With pliers or some other means, fit the kick spring back onto the stopper.
- Replace the thrust washer, sleeve, and drive shaft idle gear. The dogged side faces out.
- For '74 ~ '76 models, install the pin, O ring, sleeve, and then woodruff key on the right side of the crankshaft (Fig. 205). Fit the rotary disc matching its hub groove with the crankshaft pin.
- For '77 and '78 models, at the right side of the crankshaft, install the thrust washer, pin and splined collar, matching its notch with the pin. Install the rotary disc with the marked side facing out.



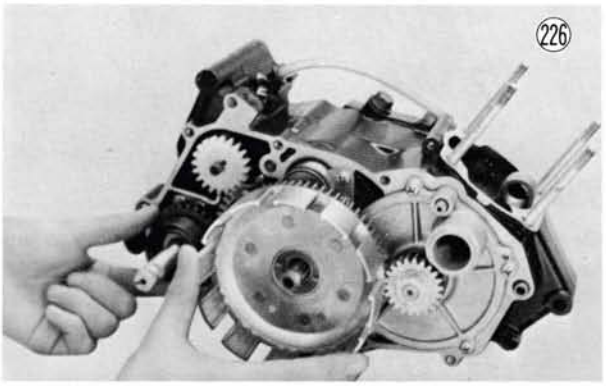
- Be sure that the large O ring is properly in place in the valve cover, and replace the cover tightening its screws with an impact driver.



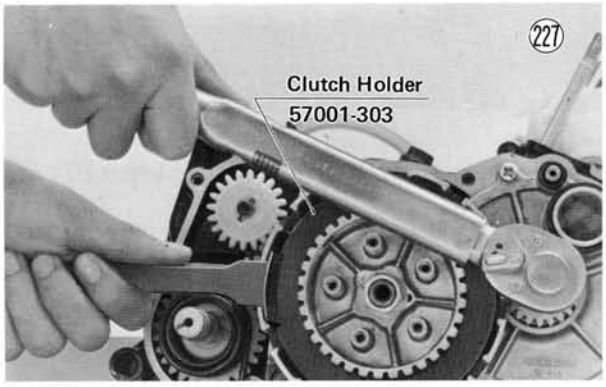
- Install the sleeve and O ring to the crankshaft ('77 and later models).
- Check to see that the woodruff key is properly positioned on the crankshaft.



- Replace the primary gear with the hole facing outward to accommodate the toothed washer. If the primary gear must be tapped into place, recheck the crankcase/crankshaft clearance. Reposition the crankshaft if necessary in the manner already described.
- Once the primary gear is fully in place, replace the toothed washer with the tooth fitted in the primary gear hole.
- Fit the spring in the external shift mechanism, and check to see that the sleeve is in place.
- Using the oil seal guide (special tool) on the crankcase shift shaft oil seal, insert the external shift mechanism back through the crankcase, and fit the pawl back onto the end of the shift drum.
- Fit the clutch housing back on the drive shaft while turning the kick gear by hand so that the rear of the housing will fit into the side of the drive shaft idle gear.



- Replace the thrust washer and then the clutch hub.
- Replace the clutch hub washer fitting its tooth in the clutch hub.
- Holding the clutch steady with the clutch holder (special tool), tighten the clutch hub nut with 8.0 ~ 11.0 kg-m (58 ~ 80 ft-lbs) of torque and the primary gear nut with 7.0 ~ 7.5 kg-m (51 ~ 54 ft-lbs) of torque.



- Bend back part of the primary gear washer over the side of the primary gear nut.

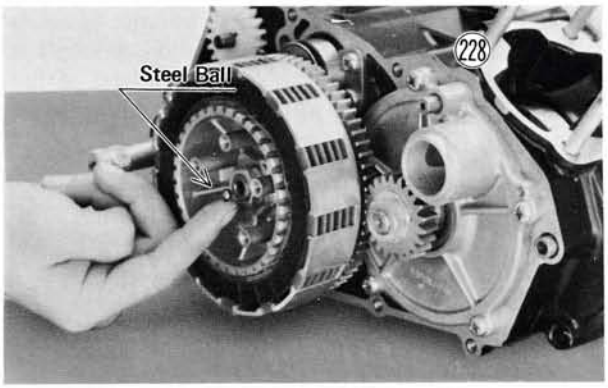
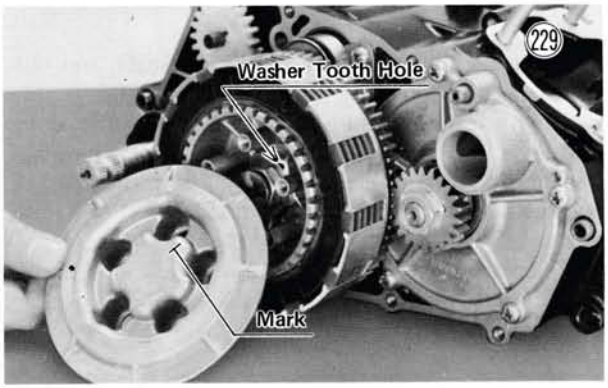
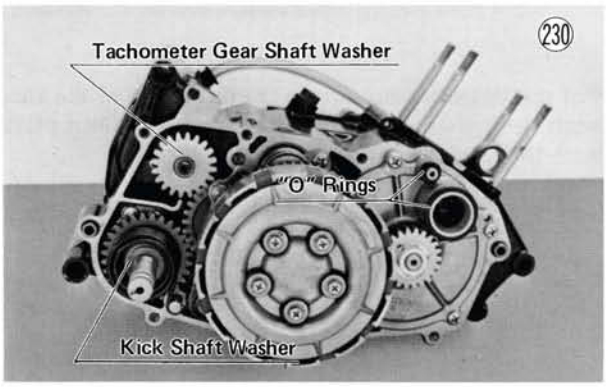
- Drop the drive shaft steel ball into the drive shaft.



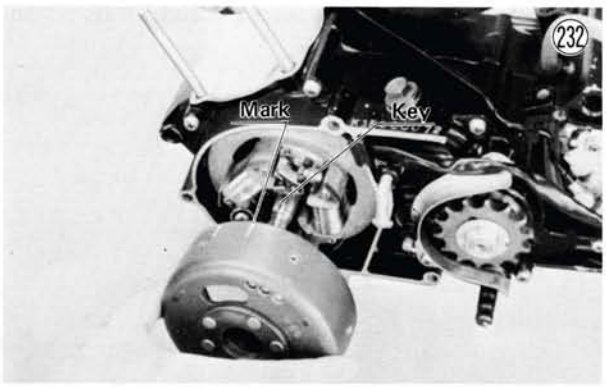
- Replace the spring plate pusher.
- Fit the spring plate back into place, aligning the mark on the plate with the washer tooth hole in the hub.



- Replace the spring bolts (5), each with its washer and spring, and tighten them evenly in a cross pattern to 0.4 ~ 0.5 kg-m (35 ~ 43 in-lbs) of torque. Tighten by hand rather than use compressed air, which might make spring pressure uneven.
- Replace the kick shaft washer and the tachometer gear shaft washer.
- Replace the rotary valve cover intake port **O** ring and the oil passage pipe **O** ring.



- Using a new right engine cover gasket, fit the right engine cover back onto the crankcase. Use an oil seal guide to protect the right engine cover oil seal, and see that the **O** ring does not fall off the rotary valve cover intake port.



- Replace the 6 mm right engine cover screws (9), and tighten them with an impact driver.
- Install the air cleaner tube to the right engine cover air duct, tightening its 5 mm screws (3).
- Replace the brake pedal back on the kickstarter shaft. Situate the brake pedal sleeve so that the cutaway fits on its knob on the crankcase.
- Replace the kick pedal.
- Note the position of the notch on the oil pump gear shaft, and then turn the oil pump shaft so that it will fit into the notch when fitting the oil pump back into place.
- Put the oil pump back into place, and tighten the oil pump mounting screws. There is a copper washer for each screw.
- Replace the oil pump input connector banjo bolt. There is a washer for each side of the connector.

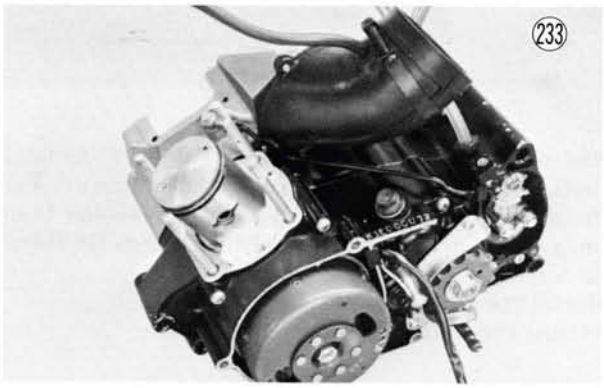
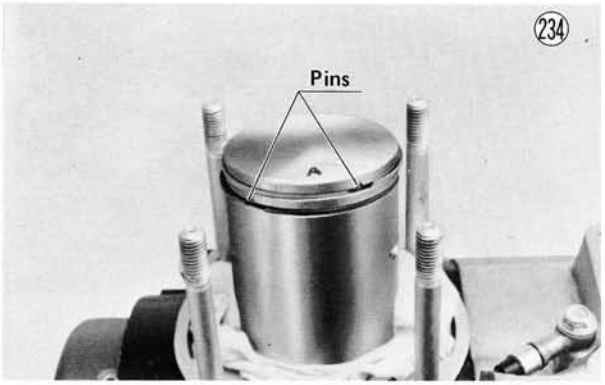
- **Bend back one side of the toothed washer over the nut.**
- Replace the engine sprocket chain guard.
- Replace the clutch push rod together with its rubber guide.
- Screw in the neutral switch.
- Replace the magneto stator, and tighten its screws (2) with an impact driver.
- Run the magneto output leads through the rubber grommet in the left crankcase half.
- Connect the light green neutral switch lead to the neutral switch.
- See that the key is fitted in its place on the crankshaft properly, and then fit the flywheel in place so that the key fits in the groove in the flywheel hub. A line on the circumference of the flywheel (of the two, the one on the right), which indicates where the key groove is located on the flywheel hub, may be referred to to facilitate installation. **(This line applied only to '74 and '75 models.)**
- Once the flywheel is all the way back in place, replace the lock washer, and tighten the magneto nut while holding the flywheel steady with the magneto flywheel holder (special tool). The maximum torque for the magneto nut is 5 kg-m (36 ft-lbs).
- Fit a piece of clean cloth into the crankcase opening **around the connecting rod so that no parts will fall into the crankcase.**
- **Apply oil to the connecting rod needle bearing, and fit it into the connecting rod.**
- Apply a little oil to the piston pin, and replace the piston and piston pin. The arrow on the top of the piston must point towards the front.

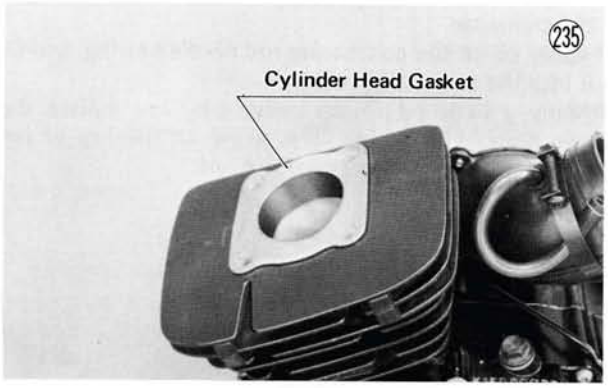


- Fit a new piston pin snap ring into the side of the piston, and turn it so that its opening does not coincide with either groove in the side of the piston.
- Remove the cloth, and fit a new cylinder base gasket into place.
- Apply a small amount of 2 stroke oil to the piston rings and the inside surface of the cylinder.
- Set the piston at BDC, and fit the base of the cylinder over the rings, pressing in on opposite sides of the rings as necessary. Be certain that the rings do not slip out of their proper position. The pin in each

piston groove must be between the ends of its piston rings.



- Replace the cylinder head gasket on the cylinder so that the gasket holes perfectly match the cylinder bore and stud holes. Only one of the four possible positions is correct. The top side (the side with the beveled inner perimeter) should face up.



- Put on the cylinder head, and insert the cylinder head nuts. Each nut has both a lock washer (next to nut head) and a flat washer. Tighten the cylinder head nuts evenly in a cross pattern with 2.2 kg-m (16 ft-lbs) of torque.
- Install the engine (Pg. 26).
- Adjust the clutch (Pg. 14).

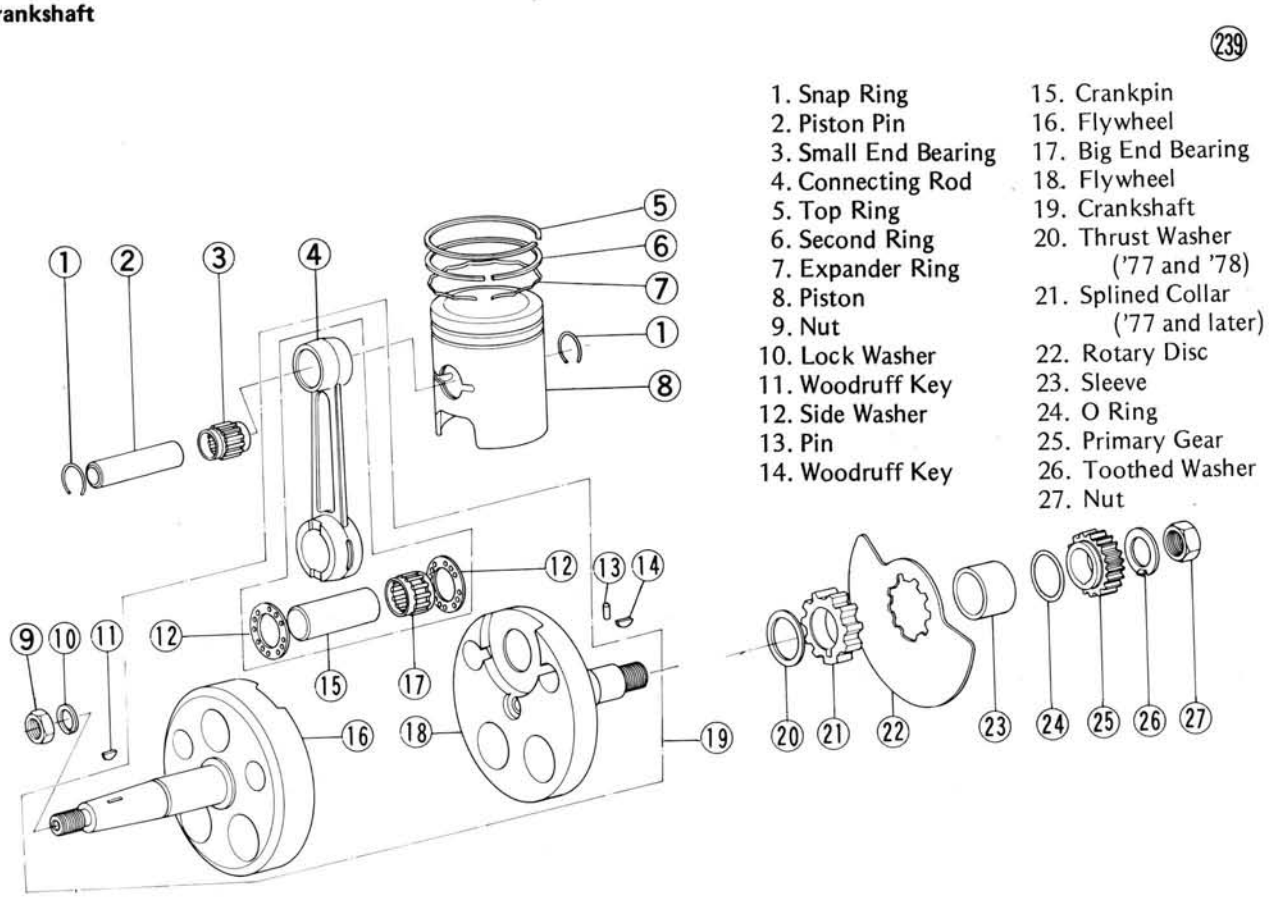
Crankshaft



Assembly Notes:

- Since the assembly of the crankshaft demands exacting tolerances, the disassembly and reassembly of the crankshaft can only be done by a shop having the necessary tools and equipment. The following information gives the tolerances that are necessary for a properly equipped shop to reassemble the crankshaft.

1. The flywheels and crankpin are cold-fitted to a tolerance of 0.073 ~ 0.094 mm (0.0029 ~ 0.0037 in).
2. Select a crankpin, needle bearing, and connecting rod such that the radial clearance will be 0.0192~0.0290 mm (0.00076~0.00114 in).
3. Press with a thickness gauge inserted between the connecting rod and one of the flywheels so that the side clearance will be 0.35 ~ 0.40 mm (0.0138 ~ 0.0157 in).
4. Supporting both ends of the crankshaft, check the crankshaft runout using a dial gauge. The flywheels must be aligned so that the runout is under 0.10 mm TIR (0.0039 in) (Pg. 103).

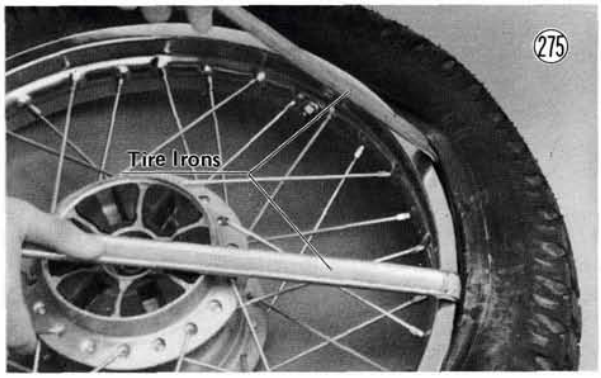
- Step on the side on the tire opposite the valve stem, and start prying the tire off the rim near the valve stem with tire irons. Take care not to insert the tire irons so deeply that the tube gets damaged.



- Remove the tube when one side of the tire is pried off.
- Pry the tire off the bead protector (if provided), and then pry the tire off the rim.

Installation:

- Put just enough air in the tube to keep it from getting caught between the tire and the rim, and insert it into the tire at this point, even if the tire was completely removed from the rim. Insert the valve stem into the rim, and screw the nut on loosely.
- If the tire was completely removed, pry one side back onto the rim, and fit the bead protector (if provided) into the tire.
- Pry the other side of the tire onto the rim, starting at the side opposite the valve. Take care not to insert the tire irons so deeply that the tube gets damaged.
- Check that the tube is not pinched between the tire and the rim, and then inflate it to the standard pressure (Pg. 118).
- Tighten the bead protector nut (if provided) and valve stem nut, and then put on the valve cap.
- Balance the wheel (Pg. 20).

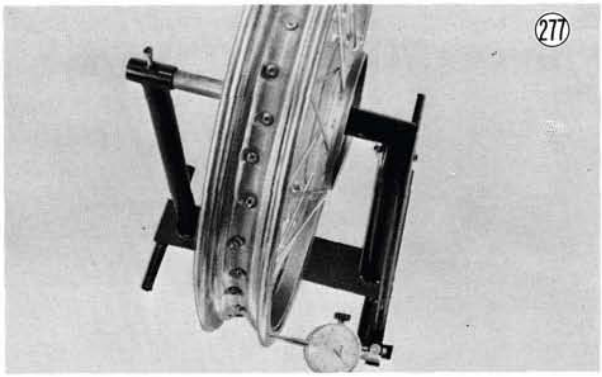
Installation:

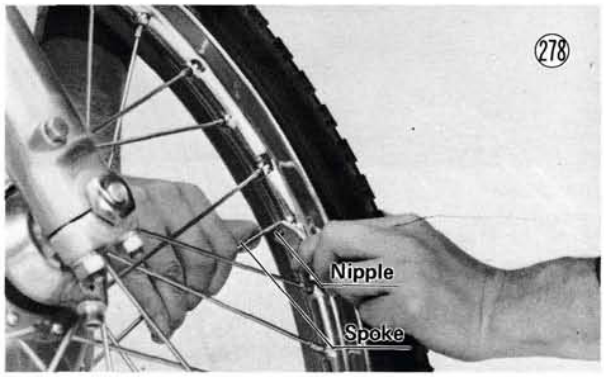
- Fit all the spokes through the holes, and screw all the nipples onto the spokes, tightening them partially.
- Suspend the wheel by the axle, and set up a dial gauge to measure rim runout. Fix the axle in place if necessary to prevent horizontal movement.



- Tighten the spokes evenly so that the radial (out from the axle) runout is less than 0.8 mm (0.032 in) and the axial (side to side) runout is less than 0.5 mm (0.020 in).
- Make sure the spokes are tightened evenly. Standard torque is 0.2~0.4 kg-m (17~35 in-lbs).
- Mount the tube and tire (Pg. 71), and balance the wheel (Pg. 20).
- Mount the wheel onto the motorcycle (Pg. 64 or 67).

SPOKE (breakage replacement)

- Reduce the tire air pressure by a small amount.
- Insert the new spoke through the hub, and bend it to meet the nipple.



- Tighten with a spoke wrench. Standard torque is 0.2 ~0.4 kg-m (17~35 in-lbs).
- Inflate the tire to standard pressure (Pg. 118).

Maintenance

AIR CLEANER

A properly cared for air cleaner ensures that only clean, filtered air is supplied through the carburetor into the engine. If the air is supplied directly without filtering, not only will dirt and dust from the air plug up carburetor passages causing the engine to run poorly, but also the dust that enters the engine will act like grinding compound wearing down the cylinder, piston, and rings. If the air cleaner element is damaged or too coarse, the result will be the same as though no element were used.

An air cleaner element clogged with dirt chokes the air supply to the engine, resulting in an overly rich fuel/air mixture and inefficient combustion. This in turn causes overheating from carbon build-up, reducing engine power.

Cleaning and replacement

The air cleaner element must be cleaned periodically (Pg. 152). In extremely dry, dusty areas, the element will need to be cleaned more often. After riding through rain or on muddy roads, the element should be cleaned immediately.

Remove the air cleaner element (Pg. 29), clean it in a bath of a high flash-point solvent, and squeeze it dry. After cleaning, saturate the element with SE class SAE 30 oil, squeeze out the excess, then wrap it in a clean rag and squeeze it dry as possible. Be careful not to tear the element. Oil it again any time it dries out.

Since repeated cleaning opens the pores of the element, replace it with a new one in accordance with the Periodic Maintenance Chart (Pg. 152). Also if there is a break in the element material or any other damage to the element, replace the element with a new one.

CARBURETOR

The carburetor (Fig. 355) performs the function of mixing the fuel and air in the proportions necessary for good engine performance at varying speeds and loads. In order for it to function satisfactorily, it must be kept well adjusted and maintained. The carburetor cable (Pg. 9) and idling speed (Pg. 11) adjustments are covered in the Adjustment Section. The discussion here concerns the fundamentals of carburetor operation, special adjustments, and the cleaning and replacement of carburetor parts.

One of the basic principles in carburetor operation is that the pressure exerted by a moving body of air is less than atmospheric pressure. As the engine draws air in through the carburetor bore, the air pressure in the carburetor bore is less than the air pressure in the float chamber, which is at atmospheric pressure. This difference in air pressure forces the fuel up through the passages into the carburetor bore where it is then atomized by the air flowing at high speed to the engine.

Another important principle is the Venturi Principle, which states that when an air passage narrows, moving air flows faster, exerting even less pressure. For example, especially at lower speeds the amount of the cutaway on the throttle valve makes use of this principle in determining the speed and thus the pressure of the air passing below it.

The amount of fuel passing through a jet depends both on the size of the jet (variable in case of the needle jet) and on the speed of the air flow over the jet. The speed of this air flow is in turn determined both by the engine rpm and by the dimensions of the passage (varied with the throttle valve) just above the jet. The size of the jet openings, the various dimensions of the air passages, and the engine arm are correlated through carburetor design so that, when properly adjusted, the carburetor meters (measures) the fuel and air in the correct proportions at different throttle openings.

The ratio of the fuel to air at different throttle openings is set through carburetor design by a number of interrelating factors, but alteration of the ratio is primarily effected through the following:

0 ~ 1/8 throttle	air screw
1/8 ~ 1/4 throttle	throttle valve cutaway, air screw
1/4 ~ 3/4 throttle	jet needle position
3/4 ~ 1 throttle	main jet size

The carburetor specifications (Table 1) have been chosen for best all around performance, and ordinarily will not require any change. However, sometimes an alteration may be desirable for improved performance under special conditions, and when proper mixture is not obtained after the carburetor has been properly adjusted and all parts cleaned and found to be functioning properly. For example, the quantity of air entering the carburetor bore is less at high altitude due to the lower atmospheric pressure. To obtain the proper carburetor fuel/air mixture, it may be necessary to raise the clip on the jet needle and to exchange the main jet for one a size smaller. In particularly cold weather, the increased density of the air may necessitate a lower clip position on the jet needle and a size larger main jet.

Since the carburetor regulates and mixes fuel and air going to the engine, there are two general types of carburetor trouble: too rich a mixture (too much fuel); too lean a mixture (too little fuel). Such trouble can be caused by dirt, wear, maladjustment, or improper fuel level in the float chamber. A dirty or damaged air cleaner can also alter the fuel to air ratio.

Table 2 Mixture Trouble Symptoms

Mixture too rich	Mixture too lean
Engine is sluggish	Engine overheats
Smoky exhaust	Runs better with choke lever pushed in
Runs worse when warm	Spark plug burned white
Spark plug fouled black	Running is unstable
Runs better without air cleaner	No power

The following explanation of the functioning and maintenance of the carburetor covers the four main systems for fuel regulation and supply: the starter system, which supplies the necessary rich mixture for starting the engine; the pilot system, which supplies fuel at idling and low speeds; the main system, which supplies fuel at medium and high speeds; and the float system, which maintains the fuel at a constant level in the float chamber.

Starter System

Fig. 356 shows the starter system, which includes the starter jet ⑤, starter pipe ④, and starter plunger ③.

The starter system is used for starting to provide the exceptionally rich fuel/air ratio that is necessary to enable easy starting when the engine is cold. When starting the engine, the throttle valve is left closed, and the starter plunger is pulled fully open by pushing the choke lever. Since the throttle valve is closed, a high intake vacuum (low pressure or suction) is developed at the engine side of the carburetor bore. The starter plunger, when raised, opens up the starter passage and an air hole so that they connect to the engine side of the carburetor bore. The intake vacuum from the engine as it is kicked over draws in air through this air hole and fuel from the float chamber through the starter passage. Fuel metered by the starter jet mixes with a small amount of air drawn in through air bleed holes in the

starter pipe as it rises in the starter passage. This small amount of air prepares the fuel for better atomization once it reaches the plunger chamber (the area just below the raised plunger) where the fuel mixes with the air drawn in through the air hole. This mixture is then drawn into the carburetor bore where it, together with a small amount of mixture supplied by the pilot system, is drawn into the engine.

In order for the starter system to work properly, the throttle must be kept closed so that sufficient vacuum can be built up at the starter outlet. Also, the choke lever must be pushed fully so that the starter plunger will fully open up the air hole and starter passage to the carburetor bore. Clogged starter pipe air bleed holes will cause insufficient atomization, thus impairing starter efficiency. Fuel mixture trouble results if, due to dirt, gum or a defective spring, the plunger does not seat properly in its rest position after the choke lever is returned.

Cleaning

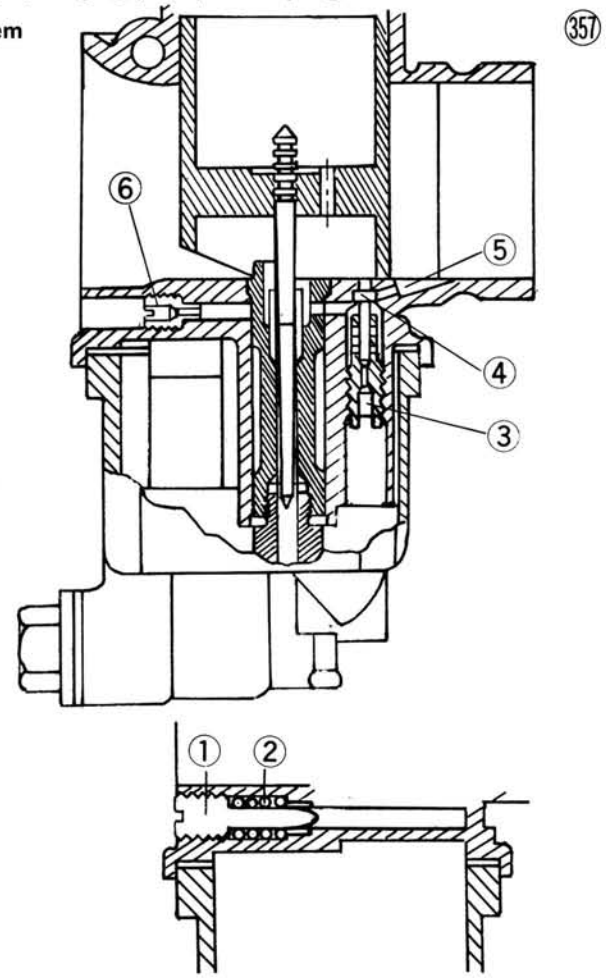
Remove the float bowl, and blow the starter pipe and the starter jet clean with compressed air. Do not clean them with wire or any other hard object which may cause damage.

Remove the starter plunger, and clean it with a high flash-point solvent.

Pilot System

Fig. 357 shows the pilot system, which includes the pilot jet ③, air screw ①, pilot outlet passage ⑤, pilot jet passage ④, and pilot air jet ⑥.

Pilot System



1. Air Screw
2. Spring
3. Pilot Jet
4. Pilot Jet Passage
5. Pilot Outlet Passage
6. Pilot Air Jet

The pilot system determines the operation of the carburetor from 0 to ¼ throttle opening. At small throttle openings, almost no fuel is drawn through the main system due to insufficient air flow past the needle jet. Instead, the fuel is drawn through the pilot jet as a result of the low pressure (suction) brought about by the demand for air by the engine and the limited but relatively fast flow of air past the pilot outlet. The low position of the throttle valve restricts the carburetor bore air flow, preventing it from relieving the low pressure created by the engine around the pilot outlet while the venturi effect (i.e., the narrower the air passage, the faster the flow of air) at the engine side of the throttle valve further reduces the low pressure.

Up to roughly 1/8 throttle valve opening, the fuel as it is drawn out of the pilot jet, located within the pilot jet passage, mixes with both air drawn in through the air screw controlled air passage and through the part of the pilot jet passage that connects to the carburetor bore. However, as the throttle valve rises further, air to the pilot jet passage is drawn in only through the air screw controlled air passage, and the fuel exits through both the pilot outlet passage and the pilot jet passage. This change of role for the upper part of the pilot jet passage is caused by the increased carburetor bore air flow, the speed of which at lower speeds is set by the throttle valve cutaway. Once the throttle valve rises, it no longer concentrates the low pressure area around just the pilot outlet.

The purpose of the pilot system is to provide the rich fuel/air mixture necessary at low engine speed. The pilot system mixture consists primarily of the fuel measured out by the pilot jet and the air let in past the air screw. Since the size of the pilot jet opening is fixed, the fuel to air ratio is controlled by the position of the air screw. As the air screw is backed out, more air is permitted to enter, making the mixture leaner. Conversely, turning the screw in restricts the air flow, making the mixture richer.

Flow Characteristics (358)

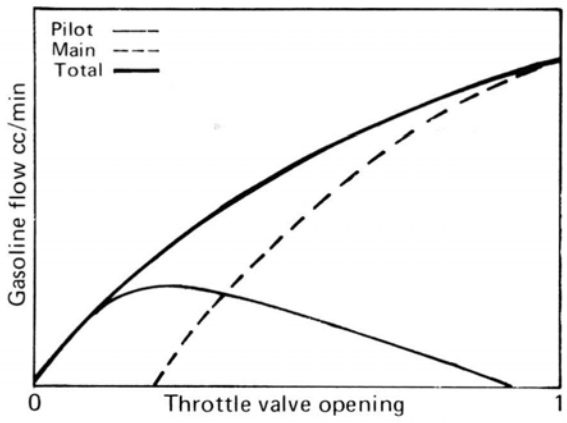


Fig. 358 shows throttle valve opening versus fuel flow for the main and pilot systems. If trouble occurs in the pilot system, not only are starting and low speed running affected, but the transition from pilot to main system is not smooth as the throttle is opened, causing a drop in acceleration efficiency. Pilot system trouble might be due to maladjustment; a dirty or loose pilot jet; or clogging of the pilot outlet passage, pilot jet passage, or air screw air passage.

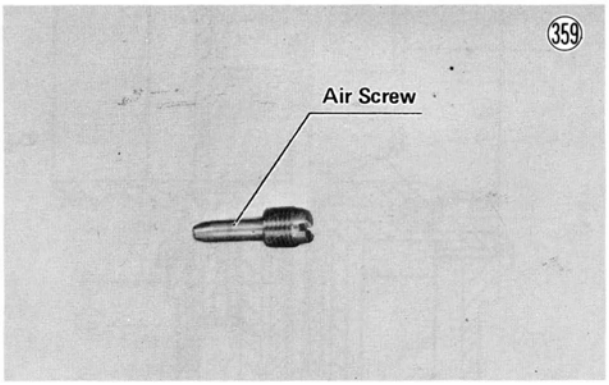
Cleaning and replacement

Wash the pilot jet with a high flash-point solvent, and blow it clean with compressed air. Also use compressed air to clean the pilot outlet passage, pilot jet passage, and air screw air passage. If necessary, use a bath of automotive-type carburetor cleaner. Do not use wire for cleaning as this could damage the jet.

Remove the air screw, and check that the tapered portion is not worn or otherwise deformed. If it is, replace the screw.



Main System

Fig. 360 shows the main system, which consists of the main jet ⑧ , main jet holder ⑩ , needle jet ④ , jet needle ③ , throttle valve ① , and air jet ② .

From about ¼ throttle opening, the air flow past the needle jet outlet is sufficient to cause most of the engine's fuel supply to be drawn through the main system. Fuel passes through the main jet holder and the main jet, through the space in the needle jet not blocked by the jet needle, and into the carburetor bore, where it is atomized by the air flow to the engine.

On one side of the needle jet is a hole to admit the air measured by the air jet. This air mixes with the fuel in the needle jet to prepare the fuel for better atomization in the carburetor bore.

The lower portion of the jet needle is tapered and extends down into the needle jet. It is fixed to the throttle valve, and thus rises up in the needle jet as the throttle valve rises. At ¼ throttle opening, the tapered portion of the needle starts coming up out of the jet, which increases needle to jet clearance and thereby increases the amount of fuel that can pass up through the jet.

The amount of fuel drawn out of the needle jet is also influenced, particularly at lower speeds, by the amount of cutaway on the throttle valve. The amount of this cutaway, which is on the intake side of the throttle valve, helps define the size of the air passage directly above both the pilot jet passage and needle jet outlets.

At near full throttle openings, the cross-sectional area of the needle to jet clearance becomes greater than the cross-sectional area of the main jet. At these openings, the fuel drawn up into the carburetor bore is limited by the size of the main jet rather than the needle to jet clearance.

Trouble in the main system is usually indicated by poor running or lack of power at high speeds. A dirty or clogged main jet will cause the mixture to become too lean. An overly rich mixture could be caused by clogging of the air jet, its air passage, or the air hole in the needle jet; by needle jet or needle wear (increasing clearance); by a loose main jet; or by a loose needle jet.

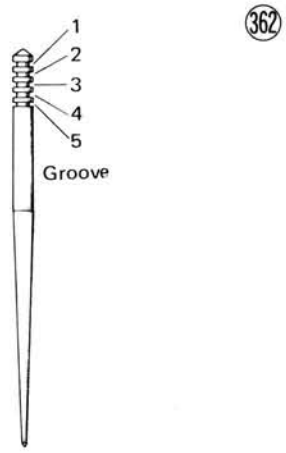
Cleaning and adjustment

Disassemble the carburetor and wash the throttle valve, main jet, needle jet, jet needle, air jet, and air passage with a high flash-point solvent, blowing them clean with compressed air. If necessary, use a bath of automotive-type carburetor cleaner. Do not use wire for cleaning as this could damage the jets.

A worn needle jet or jet needle should be replaced, although a certain amount of adjustment can be made by lowering the position of the needle. There are five grooves at the top of the needle. Changing the position of the clip to a groove closer to the top lowers the needle, which makes the mixture leaner at a given throttle opening.

NOTE: The last number of the jet needle number ("4" of 4EJ3-4) is not stamped on the needle, but is the number of the standard groove in which the clip is set. The groove numbers are counted from the top of the needle, 1 being the topmost groove, and 5 being the lowest groove.

Jet Needle



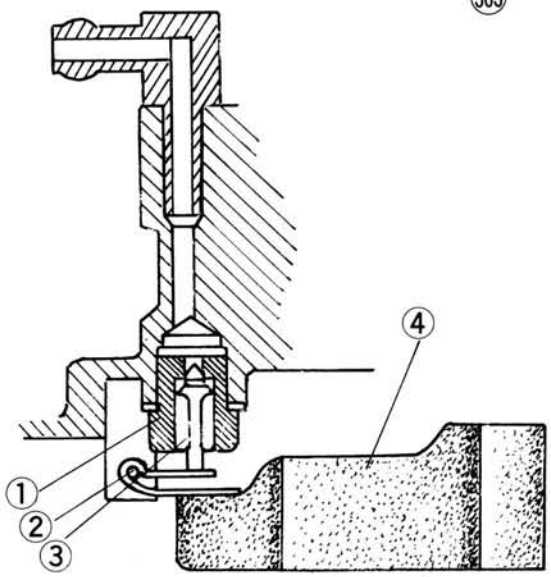
If the engine still exhibits symptoms of overly rich or lean carburetion after all maintenance and adjustments are correctly performed, the main jet can be replaced with a smaller or larger one. A smaller numbered jet gives a leaner mixture and a larger numbered jet a richer mixture. Many jets are available, but it is recommended that any change be limited to one jet size (2.5) difference from the standard jet.

Float System

Fig. 363 shows the float system, which consists of the float ④, float valve needle ③, and float valve seat ①.

The float system serves to keep a more or less fixed level of fuel in the carburetor float chamber at all times so that the fuel mixture to the engine will be stable.

Float System



1. Valve Seat
2. Float Pin
3. Valve Needle
4. Float

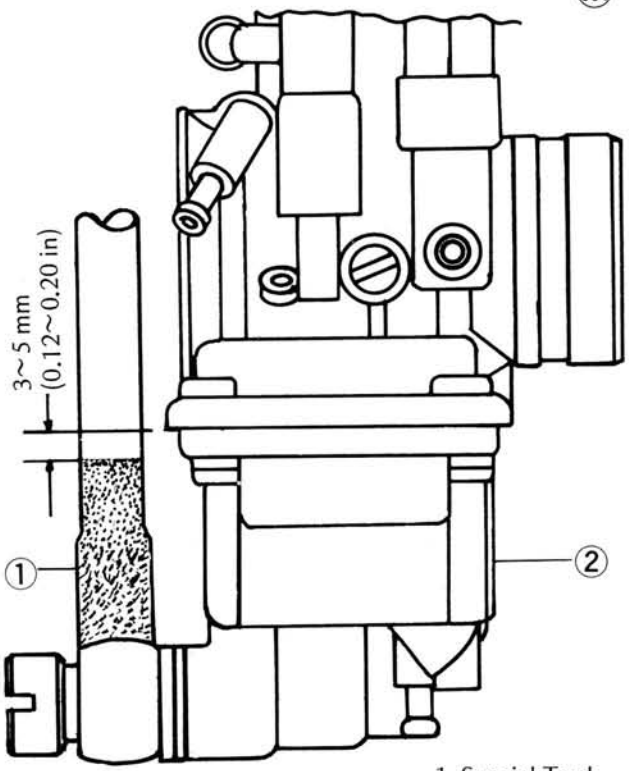
If the fuel level in the float chamber is set too low, it will be more difficult for fuel to be drawn up into the carburetor bore, resulting in too lean a mixture. If the level is set too high, the fuel can be drawn up too easily, resulting in too rich a mixture.

The fuel level is defined as the vertical distance from the center of the carburetor bore to the surface of the fuel in the float chamber. The fuel level is maintained at a constant value by the action of the float valve, which opens and closes according to the fuel level. As fuel flows through the float valve into the chamber, the fuel level rises. The float, rising with the fuel level, pushes up on the needle. When the fuel reaches a certain level, the needle is pushed completely into the valve seat, which closes the valve so that no more fuel may enter the chamber. As the fuel is drawn up out of the float chamber, the fuel level drops, lowering the float. The needle no longer blocks the float valve, and fuel once again flows through the float valve into the chamber.

Fuel level measurement and adjustment

Turn the fuel tap off, and remove the carburetor cover. Remove the main jet holder, and install in its place the fuel level measuring device (special tool). Hold the plastic tube against the carburetor body, and turn on the fuel tap. The fuel level in the plastic tube should come up to 3~5 mm (0.12~0.20 in) below the edge of the carburetor body.

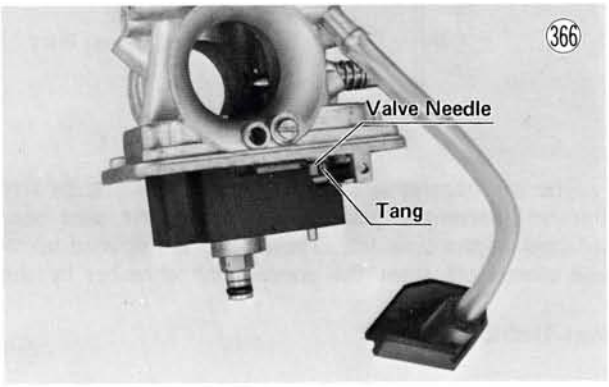
Fuel Level Measurement (364)



1. Special Tool
2. Float Bowl

If the fuel level is incorrect, remove the carburetor (Pg. 34), and then remove the float bowl and float. Bend the tang on the float a very slight amount to change the fuel level. Bending it up closes the valve sooner and lowers the fuel level; bending it down raises the level.

After adjustment, measure the fuel level again, and readjust if necessary.



Cleaning and replacement

If dirt gets between the needle and seat, the float valve will not close and fuel will overflow. Overflow can also result if the needle and seat become overworn. If the needle sticks closed, no fuel will flow into the carburetor.

Remove the carburetor, and take off the float bowl and float. Wash the bowl and float parts in a high flash-point solvent. Use carburetor cleaner if necessary. Blow out the fuel overflow pipe with compressed air.

Examine the float, and replace if damaged. If the needle is worn as shown in the diagram, replace the needle and seat as a set.

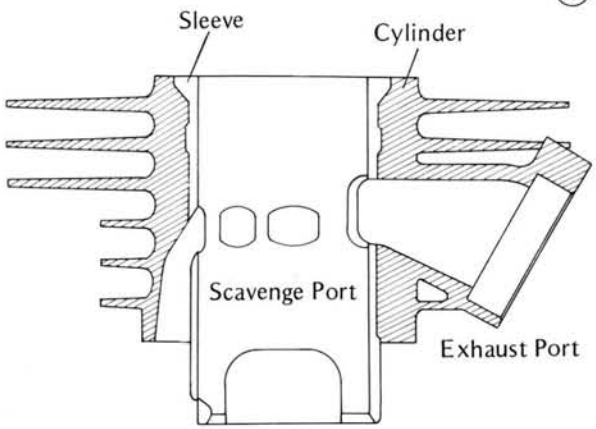
CYLINDER AND PISTON

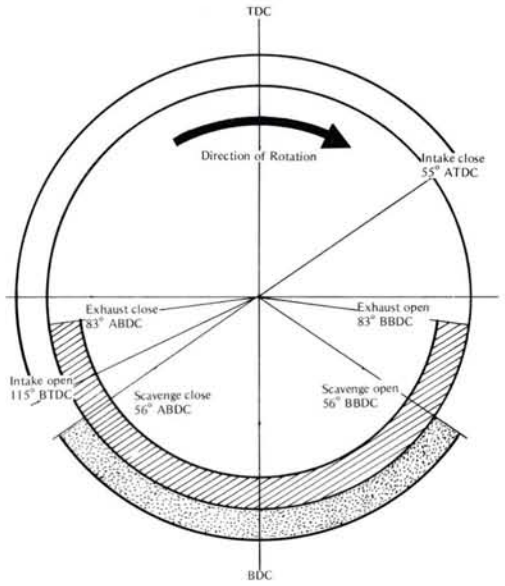
The cylinder, being part of the combustion chamber, is subjected to extremely high temperatures. Since excessive heat can seriously distort the shape of the cylinder or cause piston seizure, the cylinder is made of aluminum alloy for good heat conduction, and the outside is finned to increase the heat radiating surface for better cooling efficiency. To minimize distortion from heat and to maximize durability, a heat durable, wear resistant sleeve is casted in the cylinder.

Cylinder Construction (368)

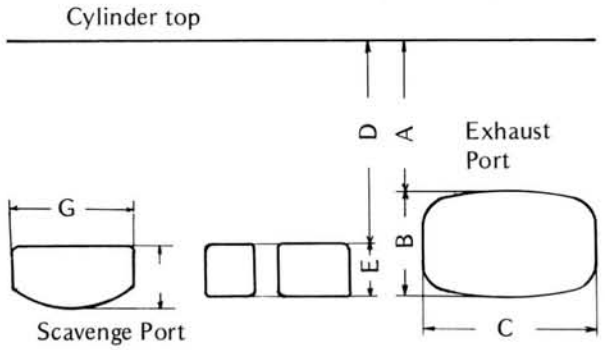


The gas transfer and exhaust are performed by five transfer (scavenge) ports and one exhaust port constructed in the cylinder. These ports are opened up to and closed off from the combustion chamber by the piston as it moves up and down inside the cylinder. The port timing, determined by the port size and position in relation to the moving piston, has been chosen so that the transfer of the fuel/air mixture from the crank chamber and the expulsion of the burned gases from the combustion chamber are timed for the most efficient engine performance. The intake process, on the other hand, is not carried out through an intake port in the cylinder, but is performed by a rotary disc, which opens and closes an intake port in the side of the crankcase.

Port Timing (369)



Port Measurement (370)



The piston is made from an aluminum alloy, which expands and distorts slightly from heat during engine operation. So that the piston will become cylindrical after heat expansion, it is designed so that when cold it is tapered in towards the head and is elliptical rather than perfectly round. The piston diameter is made so that there is enough clearance between the piston and cylinder to allow for expansion.

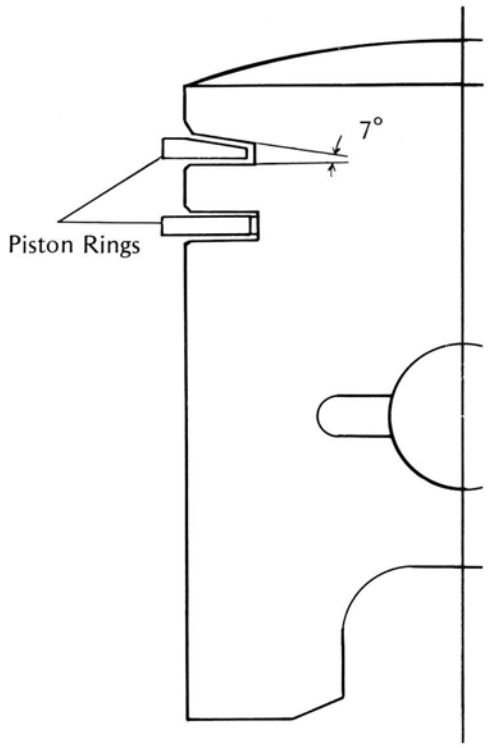
Two piston rings are fitted into grooves near the top of the piston so that gas does not escape between the piston and the cylinder wall into the crank chamber. The upper ring (top ring) is the Keystone type, the upper surface of which slants approximately 7°, while the standard type supplemented with an expander ring to preserve ring pressure on the cylinder wall is used for the lower ring (second ring). To accommodate the Keystone ring, the upper surface of the upper piston ring groove also slants approximately 7°.

The use of the Keystone rather than the standard type as the top ring provides a better compression seal, reduces the possibility of the rings sticking, and allows for better heat transfer from the piston to the cylinder.

Table 3 Port Measurements

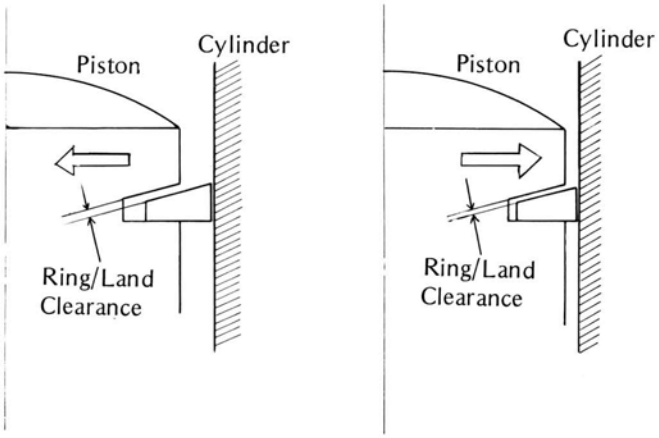
A	B	C	D	E	F	G
32.3~32.7 mm (1.27~1.29 in)	21.1~21.7 mm (0.831~0.854 in)	37.2~37.8 mm (1.46~1.49 in)	42.6 mm (1.68 in)	10.7~11.3 mm (0.421~0.445 in)	12.7~13.3 mm (0.500~0.524 in)	24.7~25.3 mm (0.972~0.996 in)

Keystone Ring Groove (371)



At the time of combustion, combustion gas pressure presses the ring down in its groove and at the same time forces it tightly against the cylinder wall due to its slanted surface. This use of combustion gas pressure minimizes gas combustion blowby, which, if excessive, impairs engine efficiency, allows combustion gum residue to accumulate causing the rings to stick, and interferes with heat transfer. Also, as the piston moves up and down, the slanted surfaces cause a rapid fluctuation in ring/land clearance resulting in a cleansing effect which inhibits the accumulation of gum residue.

Ring/Land Clearance (372)



The full floating type of piston pin is used to connect the piston to the connecting rod. The middle part of the piston pin passes through a caged needle bearing fitted into the small end of the connecting rod, and a snap ring is fitted at each end of the piston pin in a groove to prevent the pin from coming out. Since the pin is the full floating type, a small amount of clearance exists between the piston pin and the piston when the engine is at normal operating temperatures.

Proper inspection and maintenance of the cylinder and piston include checking the compression; removing carbon from the piston head, piston ring grooves, and cylinder exhaust port; and checking for wear and proper clearance during top end overhaul. Heavy carbon deposits in the combustion chamber raises compression, which results in overheating, detonation, and preignition. A worn cylinder, worn piston, or worn or stuck piston rings causes a loss of compression from gas blowby past the rings since the rings will not form a satisfactory seal between the piston and cylinder wall during compression. This gas blowby will result in difficult starting, power loss, excessive fuel consumption, and possibly engine destruction. A worn piston pin causes piston slap, which will result in accelerated piston and cylinder wear.

Engine problems may be caused not only by carbon deposits and wear or damage to the engine itself, but also by poor quality fuel or oil, improper oil, improper fuel/air mixture, improper supply of oil, or incorrect ignition timing. Whenever knocking, pinging, piston slap, or other abnormal engine noise is heard, the cause should be determined as soon as possible. Neglect of proper maintenance will result in reduced engine power and may lead to accelerated wear, overheating, detonation, piston seizure, and engine destruction.

Compression measurement

A compression test is very useful as an aid in determining the condition of the engine. Low compression may be due to cylinder wear; worn piston ring grooves; worn, broken, or sticking piston rings; cylinder head leaks; or damage to the engine such as piston seizure. Too high a compression may be due to carbon build-up on the piston head and cylinder head.

Before measuring compression, check that the cylinder head is tightened down with 2.2 kg-m (16 ft-lbs) of torque, and then thoroughly warm up the engine so that engine oil between the piston and cylinder wall will help seal compression as it does during normal running. While the engine is running, check that there is no gas leakage from around the spark plug or the cylinder head gasket.

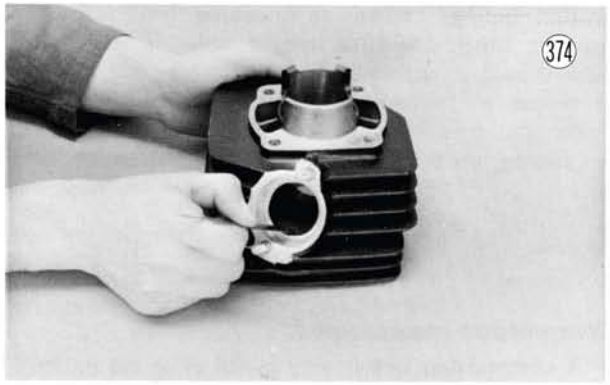
Stop the engine, remove the spark plug, and screw the compression gauge hose securely into the spark plug hole so that there will be no leakage. With the throttle fully open so that air can flow freely to the engine, turn the engine over sharply with the kick starter several times until the compression gauge stops rising. The compression is the highest reading obtainable.

Table 4 Cylinder Compression

Standard	Service Limit
11 kg/cm² (156 lbs/sq in)	7.7 kg/cm² (109 lbs/sq in)

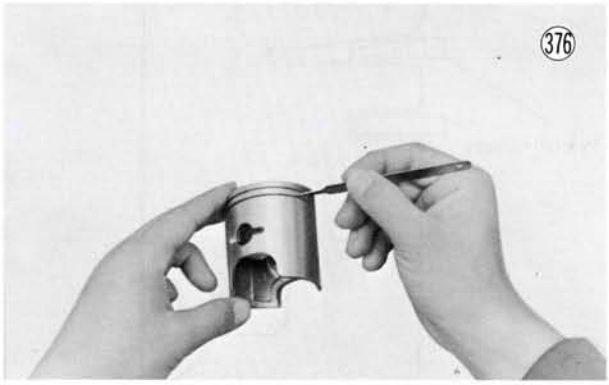
Cylinder, piston decarbonization

Carbon readily accumulates around the cylinder exhaust port, which reduces exhaust efficiency. To remove the carbon, take off the cylinder (Pg. 31), and scrape out the carbon from the exhaust port carefully. At this time, the muffler should also be inspected, and cleaned out if necessary (Pg. 133).



Built-up carbon on the piston head reduces the cooling capability of the piston and raises compression, leading to overheating which could possibly even melt the top of the piston. To decarbonize the piston head, remove the piston (Pg. 32), scrape off the carbon, and then lightly polish the piston with fine emery cloth.

Carbon, accumulated in the piston ring grooves, can cause the rings to stick. Remove the rings (Pg. 32), and clean out any carbon deposits using an end of a broken piston ring or some other suitable tool.



CAUTION: When removing carbon, take ample care not to scratch the cylinder wall, the side of the piston, or the piston ring grooves.
CAUTION: Never clean the piston head with the engine assembled. If the carbon is scraped from the piston head with the cylinder left in place, carbon particles will unavoidably drop between the piston and cylinder onto the rings and eventually find their way into the crank chamber. Carbon particles, which are very abrasive, drastically shorten the life of the rings, piston, cylinder, crankshaft bearings, and oil seals.

Cylinder, piston wear

Since there is a difference in cylinder wear in different directions, take a side to side and a front to back measurement at each of the 3 locations (total of 6 measurements) shown in Fig. 377 . If any of the cylinder inside diameter measurements exceeds the service limit, or if there is a difference of more than 0.05 mm (0.002 in) between any two measurements, the cylinder will have to be bored to oversize and then honed. However, if the amount of boring necessary would make the inside diameter greater than 57 mm (2.24 in), the cylinder must be replaced.

Cylinder Diameter Measurement

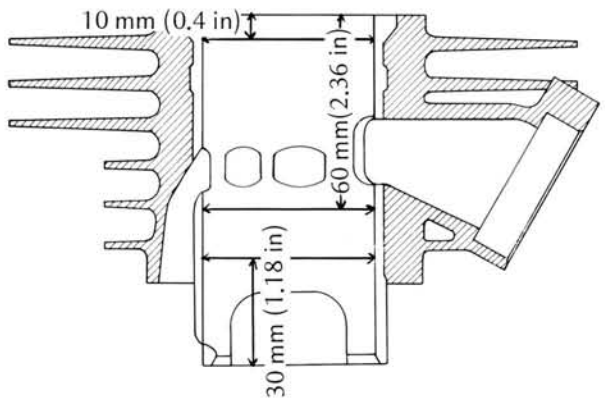


Table 5 Cylinder Inside Diameter

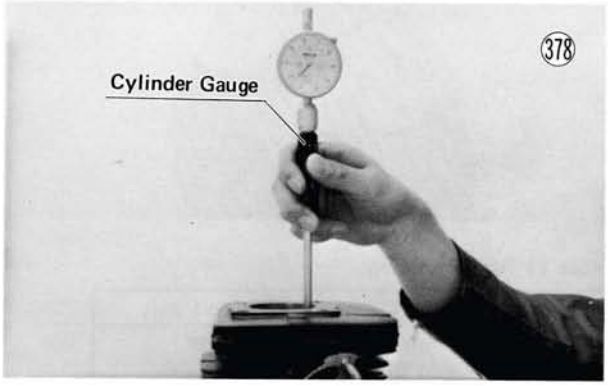
Standard	Service Limit
56.000~56.019 mm (2.2047~2.2055 in)	56.10 mm (2.209 in)



Measure the outside diameter of the piston 5 mm (0.2 in) up from the bottom of the piston at a right angle to the direction of the piston pin. If the measurement is under the service limit, replace the piston.
NOTE: Abnormal wear such as a marked diagonal pattern across the piston skirt may mean a bent connecting rod or a misaligned crankshaft.

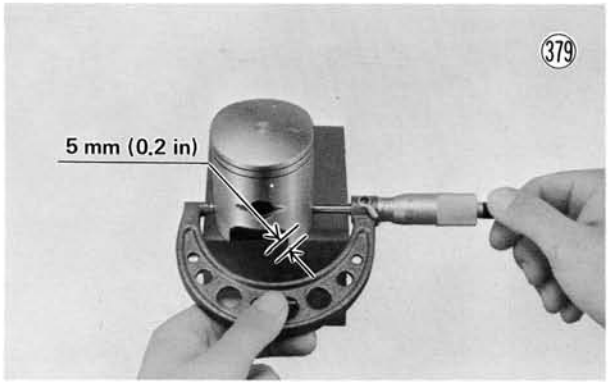


Table 6 Piston Diameter

Standard	Service Limit
55.933~55.953 mm (2.2021~2.2029 in)	55.80 mm (2.2 in)

Table 5 applies only to a cylinder that has not been bored to oversize, and Table 6 applies only to the standard size piston. In the case of a rebored cylinder and oversize piston, the service limit for the cylinder is the diameter that the cylinder was bored to plus 0.1 mm (0.004 in), and the service limit for the piston is the oversize piston original diameter minus 0.15 mm (0.0059 in). If the exact figure for the rebored diameter is unknown, it can be roughly determined by measuring the diameter at the base of the cylinder.
NOTE: Whenever the piston or cylinder has been replaced with a new one, the motorcycle must be broken in the same as with a new machine.

Piston/cylinder clearance

The piston to cylinder clearance is measured whenever the piston or cylinder is replaced with a new one, or whenever the cylinder is rebored and an oversize piston installed. The standard piston to cylinder clearance must be adhered to whenever the cylinder is replaced or rebored. However, if only the piston is replaced, the clearance may exceed the standard slightly, but it must not be less than the minimum in order to avoid piston seizure.

The most accurate way to find the piston clearance is by making separate piston and cylinder diameter measurements and then computing the difference between the two values. Measure the piston diameter as just described, and measure the cylinder diameter at the very bottom of the cylinder.

Table 7 Piston/Cylinder Clearance

Standard
0.066~0.072 mm (0.0026~0.0028 in)

Boring, honing

When boring and honing the cylinder, note the following:

1. Before boring the cylinder, first measure the exact diameter of the oversize piston, and then in accordance with the standard clearance given in Table 7, determine the diameter of the rebore.
2. Cylinder inside diameter must not vary more than 0.01 mm (0.0004 in) at any point.
3. There are two sizes of oversize pistons available: 0.5 mm (0.020 in) and 1.0 mm (0.040 in). Oversize pistons require oversize rings.
4. Be wary of measurements taken immediately after boring since the heat affects cylinder diameter.

Piston/cylinder seizure

Remove the cylinder and piston to check the damage. If there is only slight damage, the piston may be smoothed with #400 emery cloth, and any aluminum deposits removed from the cylinder with either #400 emery cloth or light honing. However, in most cases, the cylinder will have to be bored to oversize and honed, and an oversize piston installed.

Piston ring, piston ring groove wear

Visually inspect the piston rings and the piston ring grooves. If the rings are worn unevenly or damaged, they must be replaced. If the piston ring grooves are worn unevenly or damaged, the piston must be replaced and fitted with new rings.

Measure the thickness of the second ring, and measure the width of the second ring groove. If the ring has worn down to less than the service limit, replace the ring; if the groove width exceeds the service limit, replace the piston.

Table 8 Second Ring Thickness

Standard	Service Limit
1.47~1.49 mm (0.0579~0.0587 in)	1.4 mm (0.055 in)

Table 9 Second Ring Groove Width

Standard	Service Limit
1.52~1.54 mm (0.0598~0.0606 in)	1.62 mm (0.0638 in)

With the second ring in its groove, make several measurements with a thickness gauge to determine second ring/groove clearance. If the clearance exceeds the service limit, replace the second ring and/or the piston.

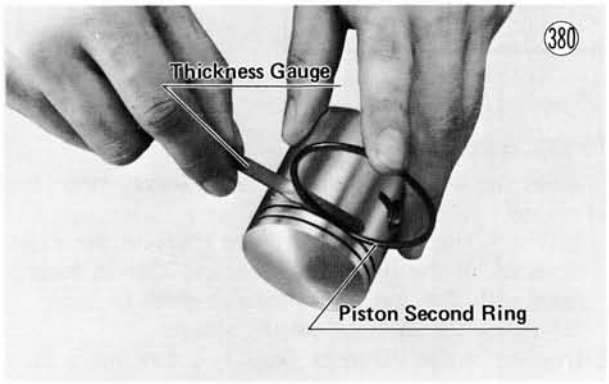

Table 10 Second Ring/Groove Clearance

Standard	Service Limit
0.03~0.07 mm (0.0012~0.0028 in)	0.17 mm (0.0067 in)

When new rings are being fitted into an old piston, check for uneven groove wear by inspecting the ring seating. The rings should fit perfectly parallel to the groove surfaces. If not, the piston must be replaced. Be sure to fit the proper Keystone ring for the top and the standard ring and expander ring for the second ring groove.

Piston ring end gap

Place the piston ring being checked inside the cylinder using the piston to locate the ring squarely in place. Set it close to the bottom of the cylinder, where cylinder wear is low. Measure the gap between the ends of the ring with a thickness gauge. If the gap is wider than the service limit, the ring is overworn and must be replaced.

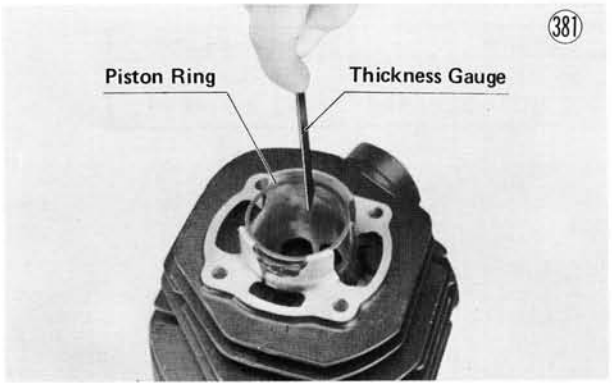

Table 11 Ring End Gap

Standard	Service Limit
0.15~0.35 mm (0.0059~0.0138 in)	0.65 mm (0.0256 in)

Piston ring tension

Piston ring tension can be evaluated by measuring the gap between the ends of the ring with the ring free of any restraint. Measure the gap before moving the rings from the piston. If the measured gap is less than the service limit, the ring is weak and must be replaced.

Table 12 Ring Free Gap

	Standard	Service Limit
Top ring	about 7.5 mm (0.295 in)	6.7 mm (0.264 in)
Second ring	about 4.5 mm (0.177 in)	4 mm (0.157 in)

Piston, piston pin, con-rod, needle bearing wear

Measure the diameter of the piston pin with a micrometer, and measure the inside diameter of both piston pin holes in the piston. If the piston pin diameter is less than the service limit at any point, replace the piston pin. If either piston pin hole diameter exceeds the service limit, replace the piston.

Measure the inside diameter of the connecting rod small end. If the diameter exceeds the service limit, replace the connecting rod.

The rollers in the needle bearings wear so little that the wear is difficult to measure. Instead, inspect the needle bearing for abrasions, color change, or other damage. If there is any doubt as to its condition, replace the needle bearing.

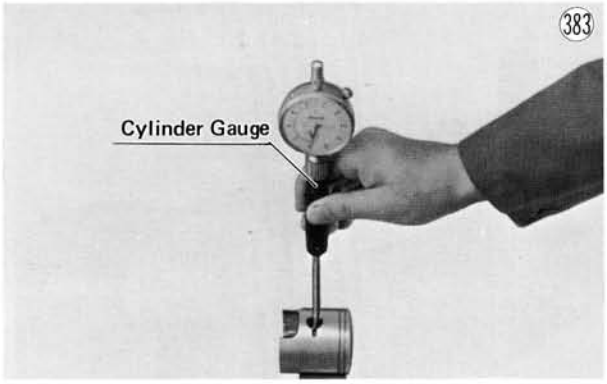

Table 13 Piston Pin, Piston Pin Hole, Small End Dia

	Standard	Service Limit
Piston Pin	13.994~14.000 mm (0.5509~0.5512 in)	13.96 mm (0.5496 in)
Piston Pin Hole	13.9985~14.0065 mm (0.5511~0.5514 in)	14.08 mm (0.554 in)
Con-rod Small End	18.003~18.014 mm (0.7088~0.7092 in)	18.05 mm (0.7106 in)

To the Dealer: When possible, match parts from stock so that a marked pin is assembled with an "A" piston and an unmarked pin with a "B" piston.

NOTE: When a new piston or pin is used, check that piston to pin clearance is 0.0024~0.0084 mm (0.00009 ~0.00033 in).

CYLINDER HEAD

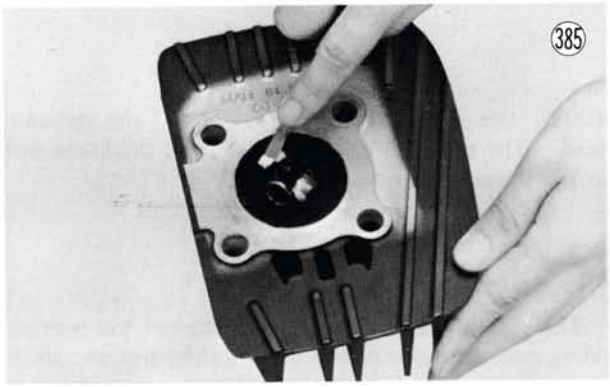
The cylinder head is made of aluminum alloy, used for its high heat conductivity, and is finned on the outside to aid dissipation of the heat generated in the combustion chamber. A copper gasket fits between the cylinder head and cylinder to prevent gas leakage. On one side of the cylinder head is the spark plug hole, and on the opposite side a hole is tapped to accommodate a decompressor.

A decompressor may be used to facilitate kick starting the engine. When the decompressor is opened for kick starting, part of the fuel/air mixture escapes during compression through an opening in the decompressor so that the kickstarter turns over more easily. However, the decompressor is not necessary under normal conditions; a bolt which has the same thread pitch, diameter, and reach is fitted in its place.

Carbon built up inside the combustion chamber interferes with heat dissipation and increases the compression ratio, which may result in preignition, detonation, and overheating. Compression leakage may be caused by damaged or dirty cylinder or cylinder head gasket surfaces, a damaged or dirty gasket, a loose spark plug, a loose decompressor hole plug, a loose or faulty decompressor, or an improper head mounting or mounting torque. Escaping hot combustion gas not only reduces engine power but could damage the cylinder head and cylinder gasket surfaces beyond repair.

Cleaning and inspection

Remove the cylinder head (Pg. 31). Scrape out any carbon, and clean the head with regular solvent.



Lay a straight edge across the cylinder head gasket surface at several different points, and measure warp by inserting a thickness gauge between the straight edge and the gasket surface. If warp exceeds the service limit, replace the cylinder head.

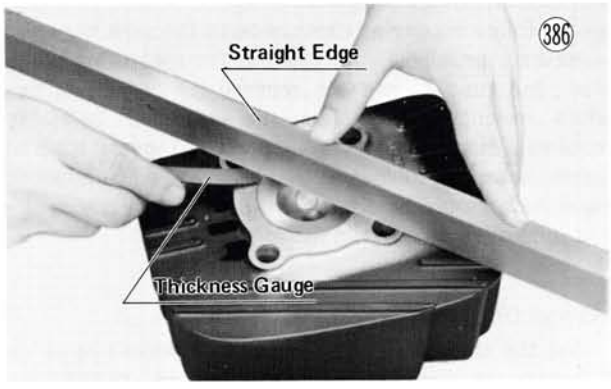


Table 14 Cylinder Head Warp

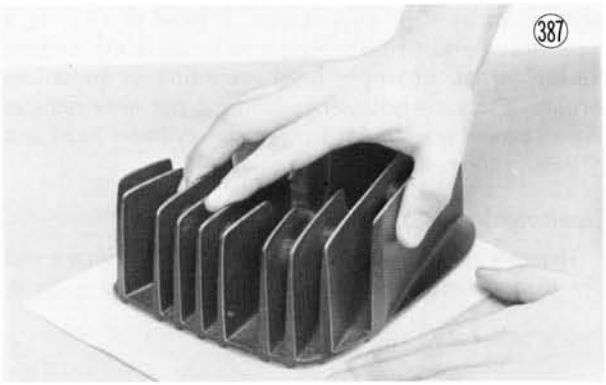
Service Limit
0.05 mm (0.002 in)

The cylinder head gasket surface may also be checked for warp or other damage by rubbing it on a surface plate coated with machinist's bluing. Repair light damage by rubbing the gasket surface on emery cloth (first #200, then #400) secured to the surface plate. After smoothing the cylinder head gasket surface, coat it with machinist's bluing, and rub it over the cylinder gasket surface; if necessary, repair the surface in the same manner that the cylinder head was repaired. Severe damage to either of the gasket surfaces necessitates replacement.



NOTE: Use only the proper gasket for the cylinder head. The use of a gasket of incorrect thickness will change the compression.

CRANKSHAFT

The crankshaft is the part that changes the reciprocating motion of the piston into rotating motion, which is transmitted to the rear wheel when the clutch is engaged. Crankshaft trouble, such as excessive play or runout, will multiply the stress caused by the intermittent force on the piston, and will result in not only rapid crankshaft bearing wear, but also noise, power loss, vibration, and a shortened engine life. A defective crankshaft should always be detected at an early stage and then repaired immediately.

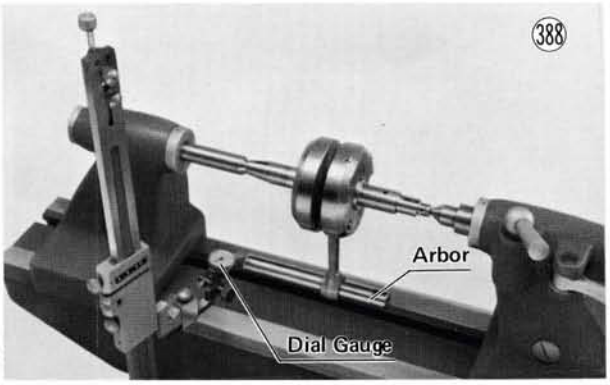
The following explanation concerns the most common crankshaft problems, the method for measuring warp, play, and runout, and the method for correcting flywheel misalignment. Since the crankshaft assembly requires a manual or hydraulic press and special tools to attain the precise tolerances that are required, a defective crankshaft should be either rebuilt by a properly equipped shop or replaced as an assembly.

Connecting rod bending, twisting

Set the crankshaft in a flywheel alignment jig or on V blocks on a surface plate. Select an arbor of the same diameter as the piston pin and of optional length, and insert it through the small end of the connecting rod.

Using a height gauge or dial gauge, measure the difference in the height of the rod above the surface plate over a 100 mm (4 in) length to determine the amount the connecting rod is bent.

Using the arrangement shown in Fig. 389 , measure the amount that the arbor varies from being parallel with the crankshaft over a 100 mm (4 in) length of the arbor to determine the amount the connecting rod is twisted.



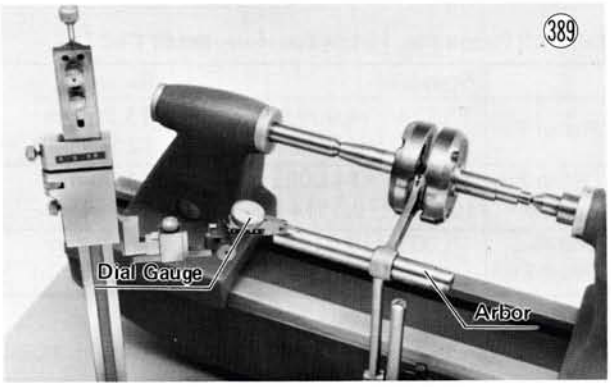


Table 15 Connecting Rod Bend, Twist

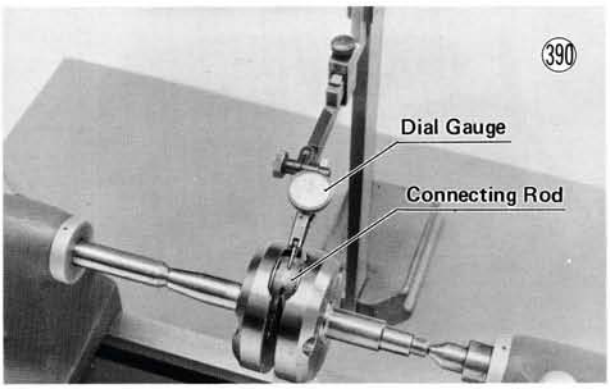
Standard	Service Limit
under 0.05 mm/100 mm (under 0.0020 in/4 in)	0.20 mm/100 mm (0.079 in/4 in)

If either of the above measurements exceeds the service limit, the connecting rod or the crankshaft assembly must be replaced.

Connecting rod big end radial clearance

Set the crankshaft in a flywheel alignment jig or on V blocks, and place a dial gauge against the big end of the connecting rod. Push the connecting rod first towards the gauge and then in the opposite direction. The difference between the two gauge readings is the radial clearance.



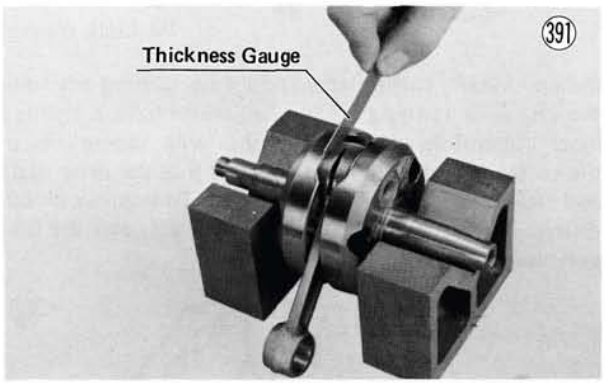
If the radial clearance exceeds the service limit, the crankshaft should be either replaced or disassembled and the crankpin, needle bearing, and connecting rod big end examined for wear.

Table 16 Connecting Rod Radial Clearance

Standard	Service Limit
0.0192~0.029 mm (0.0008~0.0011 in)	0.08 mm (0.0031 in)

Connecting rod side clearance

Measure the side clearance of the connecting rod with a thickness gauge as shown in the figure. If the measured value exceeds the service limit, the crankshaft should be either replaced or disassembled and the side washers examined for wear.



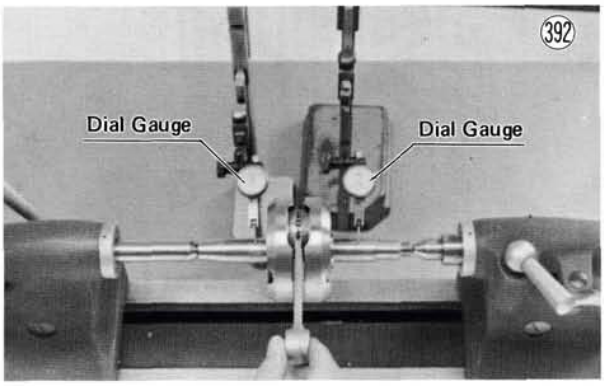
391

Table 17 Connecting Rod Side Clearance

Standard	Service Limit
0.35~0.40 mm (0.014~0.016 in)	0.6 mm (0.024 in)

Crankshaft runout

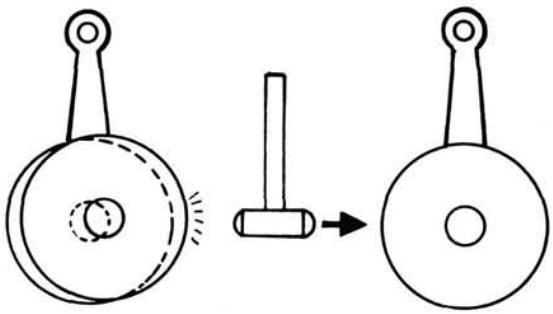
Set the crankshaft in a flywheel alignment jig, and place a dial gauge to the points indicated. Turn the crankshaft slowly. The maximum difference in gauge readings is the crankshaft runout.



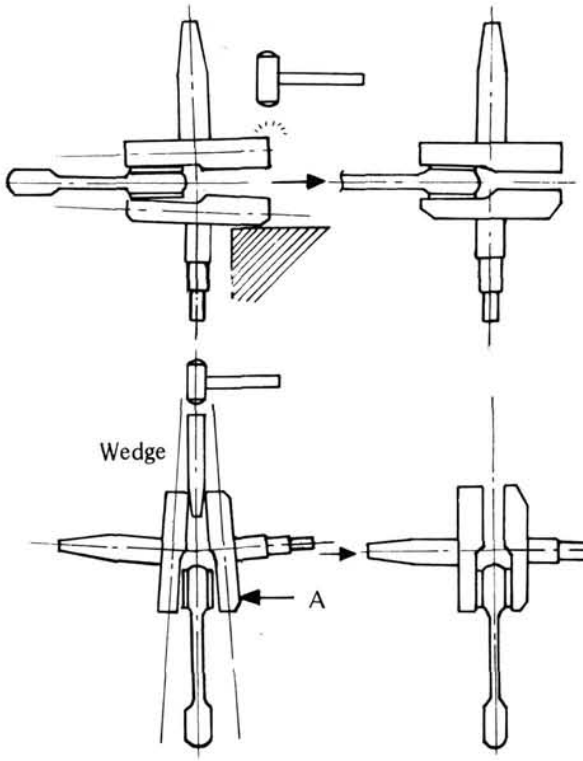
392

If the runout at either point exceeds the service limit, align the flywheels so that the runout falls within the service limit. As shown in Figs. 393, 394, and 395, there are three types of flywheel misalignment.

Flywheel Horizontal Misalignment 393



Flywheel Vertical Misalignment 394



395

In the case of horizontal misalignment, which is the most common, strike the projecting rim of the flywheel with a plastic, soft lead, or brass hammer as indicated in the figure. Recheck the runout with a dial gauge, repeating the process until the runout falls within the service limit. Vertical misalignment is corrected either by driving a wedge in between the flywheels or by squeezing the flywheel rims in a vise, depending on the nature of the misalignment. In case of both horizontal and vertical misalignment, correct the horizontal misalignment first.

If flywheel misalignment cannot be corrected by the above method, replace the crankpin or the crankshaft itself.

NOTE: Don't hammer the flywheel at part "A".

Table 18 Crankshaft Runout

Standard	Service Limit
under 0.04 mm (under 0.0016 in)	0.10 mm (0.0039 in)

Big end seizure

In case of serious seizure with damaged flywheels, the crankshaft must be replaced. In case of less serious damage, disassemble the crankshaft and replace the crankpin, needle bearing, side washers, and connecting rod.

CLUTCH

Fig. 397 shows an exploded view of the clutch, which is a wet, multi-plate type with 5 friction plates ⑧, 4 steel plates ⑨, and 5 steel rings ⑩. The friction plates are made from cork, used for its high coefficient of friction, and bonded on a bakelite core, which provides durability and warp resistance. The clutch housing ④ has a reduction drive gear riveted to one side and contains damper rubbers to absorb shock from the drive train.

The clutch release mechanism is shown in Fig. 396. The clutch release rack ⑤ and pinion ④ are both made of steel. Assembled into the center of the rack is the clutch adjusting screw ②, which pushes on the push rod ⑧ inside the drive shaft to release the clutch.

The friction plates are connected to the clutch housing by tangs on the outer circumference of each plate, and, since the clutch housing is gear-driven directly by the crankshaft, these plates are always turning any time the engine is running. The steel plates have a toothed inner circumference, which meshes with the splines in the clutch hub on the drive shaft so that the drive shaft and steel plates always turn together. To improve clutch disengagement, steel rings are inserted between the friction and steel plates.

One end of each clutch spring forces against its washer and bolt, which threads into the clutch hub, and the other end forces against the spring plate. When the clutch is left engaged, the springs pressing against the spring plate force the spring plate, friction and steel plates, steel rings, and clutch hub tightly together so that the friction plates will drive the steel plates by virtue of their mutual friction and thereby transmit the power to the transmission drive shaft.

When the clutch lever is pulled to release (disengage) the clutch, the clutch cable pulls the clutch release lever turning the release shaft. The release pinion, which is part of the release shaft, moves the rack in the direction of the clutch. The clutch adjusting screw in the center of the rack then pushes the push rod, which through the steel ball and spring plate pusher pushes the spring plate. Since the spring plate moves the same distance that the release rack moves and the clutch hub remains stationary, the spring pressure is taken off the clutch plates. Because the plates are no longer pressed together, the power transmission from the crankshaft to the transmission drive shaft is interrupted. However, as the clutch lever is released, the clutch springs return the spring plate and once again force the spring plate, plate assembly, and clutch hub tightly together.

A clutch that does not properly disengage will cause shifting difficulty and possible transmission damage. On the other hand, a slipping clutch will reduce power transmission efficiency and may overheat and burn out. A clutch that does not properly disengage may be caused by:

1. Excessive clutch lever play.
2. Clutch plates that are warped or too rough.
3. Uneven clutch spring tension.
4. Deteriorated transmission oil.
5. Transmission oil of too high a viscosity.
6. The clutch housing frozen on the drive shaft.
7. A defective clutch release mechanism.
8. Insufficient clutch release lever angle.
9. An unevenly worn clutch hub or housing.

A slipping clutch may be caused by:

1. No clutch lever play.
2. Worn friction plates.
3. Weak clutch springs.
4. The clutch cable not sliding smoothly.
5. A defective clutch release mechanism.
6. An unevenly worn clutch hub or housing.

Clutch noise may be caused by:

1. Too much backlash between the primary gear and the clutch gear.
2. Damaged gear teeth.
3. Too much clearance between the friction plate tangs and the clutch housing.
4. Deteriorated damper rubber.
5. Metal chips jammed into the clutch housing gear teeth.

Clutch spring tension

Clutch springs that have become weak will not return to their original length when disassembled from the clutch. Their condition can thereby be determined by measuring the free length with vernier calipers.

If any spring is shorter than the service limit, replace all the springs as a matched set to ensure even tension on the clutch plates.

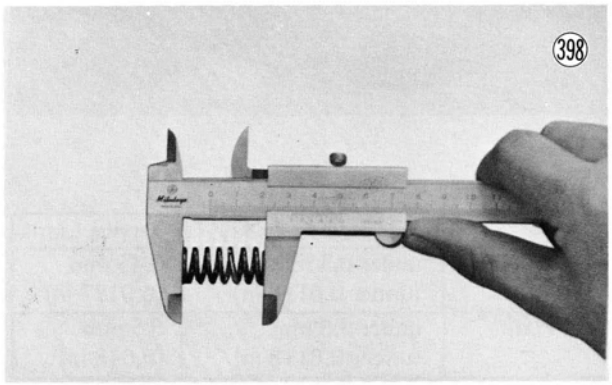

Table 19 Clutch Spring Free Length

Standard	Service Limit
33.1 mm (1.3 in)	31.6 mm (1.24 in)

Friction plate wear, damage

Visually inspect the friction plates to see whether or not they show any signs of heat seizure or have become rough or unevenly worn. Measure the thickness of the plates with vernier calipers.

If any plates show signs of damage, or if they have worn past the service limit, replace them with new ones.

Friction Plate Measurement

Table 20 Friction Plate Thickness

Standard	Service Limit
2.9~3.1 mm (0.114~0.122 in)	2.5 mm (0.098 in)

Clutch plate warp

Place each friction plate and each steel plate on a surface plate, and measure the gap between each clutch plate and the surface plate. This gap is the amount of clutch plate warp.

Replace any plates warped over the service limit.

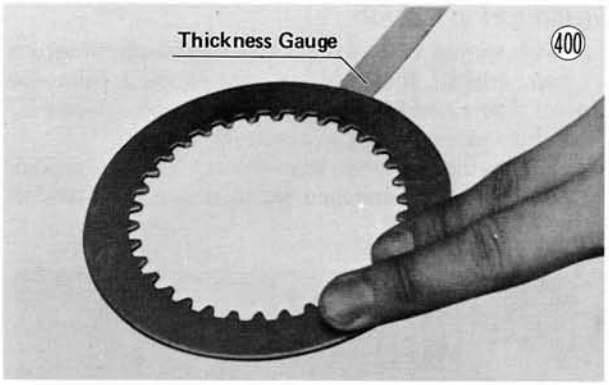

Table 21 Clutch Plate Warp

	Standard	Service Limit

Steel Plate	under 0.3 mm (under 0.0118 in)	0.5 mm (0.018 in)

Friction plate/clutch housing clearance

Measure the clearance between the tangs on the friction plates and the fingers of the clutch housing. If this clearance is excessive, the clutch will be noisy.

If the clearance exceeds the service limit, replace the friction plates. Also, replace the clutch housing if it is unevenly or badly worn where the friction plates wear against it.

Friction Plate/Clutch Housing Clearance (401)

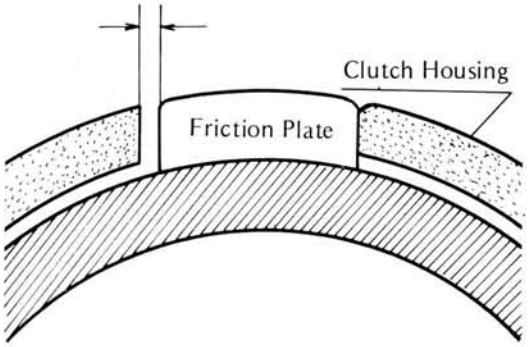

Table 22 Friction Plate/Clutch Housing Clearance

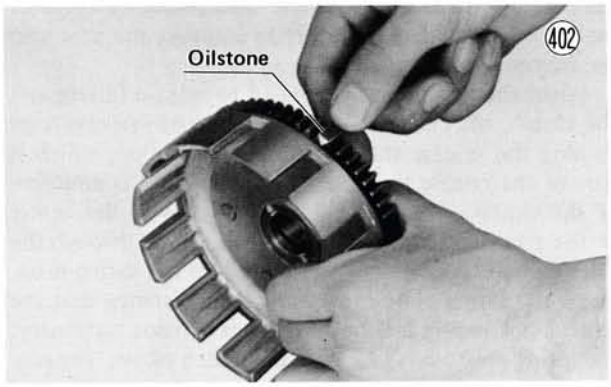
Standard	Service Limit
0.05~0.45 mm (0.114~0.122 in)	0.65 mm (0.026 in)

Clutch housing gear damage

Inspect the teeth on the clutch gear. Any light damage can be corrected with an oilstone, but the clutch housing must be replaced if the teeth are badly damaged.

Damaged teeth on the clutch housing gear indicate that the teeth on the primary gear, by which it is driven, may also be damaged. At the same time that the clutch housing gear is repaired or replaced, the primary gear should be inspected, and then repaired or replaced if necessary.



Clutch housing/primary gear backlash

Measure the backlash between the clutch housing gear and primary gear with a dial gauge. Set the dial gauge against a tooth on the clutch housing gear, and rotate the clutch housing gear back and forth while keeping the primary gear stationary. The difference between the highest and lowest dial reading is the amount of backlash. If the amount of backlash exceeds the service limit, replace both the clutch housing and the primary gear.

Clutch housing/drive shaft sleeve wear

Measure the diameter of the drive shaft sleeve with a micrometer, and measure the inside diameter of the clutch housing. Find the difference between the two readings to determine the clearance. Replace the sleeve if the clearance exceeds the service limit.

Table 24 Clutch Housing/Drive Shaft Sleeve Wear

Standard	Service Limit
0.020~0.054 mm (0.0008~0.0021 in)	0.154 mm (0.0061 in)

Clutch hub damage

Inspect where the teeth on the steel plates wear against the splines of the clutch hub. If there are notches worn into the splines, replace the clutch hub.

Clutch release rack and pinion wear

Visually inspect the clutch release rack and pinion for damage or excessive wear. If there is any damage or excessive wear, replace the rack and shaft as a set.

Fit the rack and shaft into the left engine cover, and turn the shaft back and forth while holding the rack steady to check rack and pinion movement. If there is excessive play, replace the rack and shaft as a set.

Lubrication

Apply grease liberally to the clutch release shaft, release rack, and inside the holes (2) in the left engine cover.

TRANSMISSION

The transmission is a 6-speed, constant mesh, return shift type. Its cross section is shown in Fig. 404, and the shift mechanism is shown in Fig. 405. For simplicity, the drive shaft gears in the following explanation will be referred to as "D" (e.g., D1=drive shaft 1st gear) and the output shaft gears as "O".

Gears D3 & D4 (single unit), O5, and O6 are all splined and thus rotate along with their shaft. During gear changes these gears are moved sidewise on their shaft by the 3 shift forks, one for each gear. Gears D2, D5, O1, O2, O3, and O4 rotate free of shaft rotation, but cannot move sidewise. Gears D1 and D6 are fixed in place on the drive shaft, rotating along with the shaft and unable to move sidewise.

When the shift pedal ① is raised or lowered, the gear change shaft ③ turns, a pawl ⑧ on the external shift mechanism arm ④ catches on one of the shift drum pins ⑬, and the shift drum ㉔ turns. As the shift drum turns, the shift fork guide pins (3) ㉕, each riding in a groove in the shift drum, shift the position of one or another of the shift forks ⑯ ㉗ ㉘ in accordance with the winding of the grooves. The shift fork fingers then determine the position of gears D3 & D4 ⑰, O5 ㉚, and/or O6 ㉙. Refer to Figs. 406 to 412 for the gear train for neutral and each of the six gears.

A spring ⑦ is fitted on the external shift mechanism to keep the shift arm pressed against the shift drum pins to ensure proper pawl and pin contact. When the shift pedal is released after shifting, the return spring ⑥, returns the pawl and shift pedal back to their original positions. So that the transmission will remain where it was shifted, another spring, the shift drum positioning pin spring ⑳, pushes the shift drum positioning pin ㉑ into one of seven positions on the shift drum operating plate ㉓. Six of these positions are equally spaced and correspond to the six gears. The other position is halfway between the position for 1st and 2nd gears and corresponds to the half-stroke shift pedal movement from 1st or 2nd gear required to shift into neutral.

The return spring pin ⑤ on the side of the crankcase passes through a cutout on the shift mechanism. Each time that the shift pedal is operated, the pin limits the shift mechanism's range of movement, stopping the shift mechanism after the pawl on the shift mechanism arm has rotated the shift drum the proper amount for gear change. The return spring pin thus prevents the drum from being rotated too far.

A neutral indicator light is provided so that the rider can readily determine whether or not the transmission is in neutral. The neutral indicator switch, installed in the crankcase near the magneto flywheel, consists of a spring loaded pin which comes into contact with a nub on the side of the shift drum whenever the transmission is in neutral. When the shift drum has shifted the transmission into neutral, the neutral indicator switch pin touching this nub completes the neutral indicator light circuit, which turns the neutral indicator light on.

The transmission oil, when at its proper level, supplies a lubricative film to the surfaces of all moving transmission parts; oil reaches even the gear inside circumference in the case of the output shaft idle gear and the alloy hubbed gear O1 through oil holes in the output

shaft. However, oil that has been allowed to become deteriorated or contaminated will result in rapid wear and possible heat seizure of transmission parts. The oil must always be kept at its proper level and changed whenever necessary (Pg. 153).

Transmission or external shift mechanism damage, causing the transmission to misshift, overshift, and/or jump out of gear, brings about more damage to the transmission and also overrev damage to the engine itself. An improperly functioning transmission or external shift mechanism may be caused by the following:

1. Loose return spring pin
2. Broken or weakened return spring or shift drum positioning pin spring
3. Broken or weakened shift pawl spring
4. Damaged shift mechanism arm
5. Loose shift drum stopper
6. Bent or worn shift fork(s)
7. Worn shift fork groove on gear D3 & D4, O5, and/or O6.
8. Worn shift fork guide pin(s)
9. Worn shift drum groove(s)
10. Worn or damaged gear dogs, gear dog holes, and/or gear dog recesses
11. Improperly functioning clutch or clutch release
12. Improper assembly or missing parts

Transmission noise results from worn or damaged shafts, gear hubs or teeth, crankcase bearings, etc.

The idle gears on the output shaft and drive shaft are constantly meshed, and transmit the rotation of the kick gear through the clutch housing gear to the primary gear when the engine is started. Since these gears are not directly related to the transmission, they are covered in the Kickstarter section (Pg. 111).

External shift mechanism inspection

Inspect the shift pawl spring, shift pawls, and return spring. Replace any broken or otherwise damaged parts.

Measure the free length of the shift pawl spring. If it is less than the service limit, replace it with a new one.

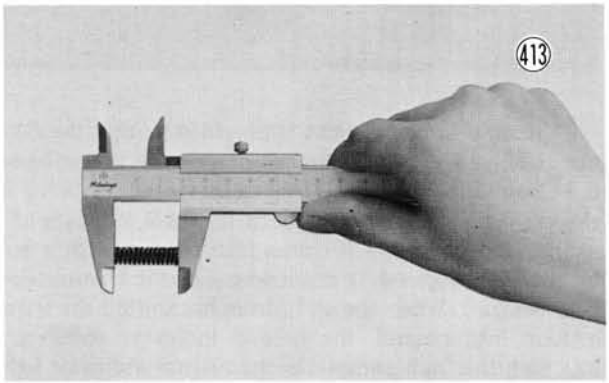

Table 25 Shift Pawl Spring Free Length

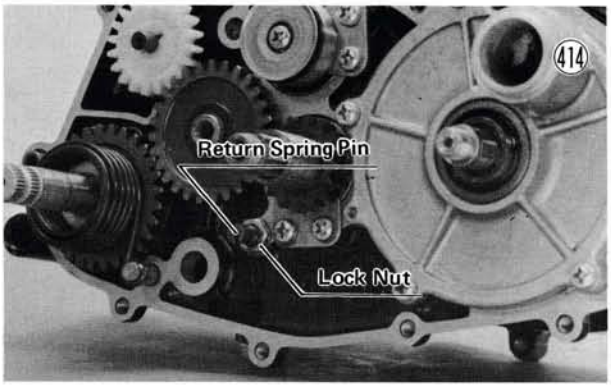
Standard	Service Limit
27.9 mm (1.10 in)	26.5 mm (1.04 in)

Check to see if the return spring pin is loose or not. If it is loose, remove it and apply a locking agent to the threads. Then screw it back in tightening its lock nut.



Shift fork bending

Visually inspect the shift forks, and replace any fork that is bent. A bent fork could cause difficulty in shifting or allow the transmission to jump out of gear when under power.

Shift fork/gear groove wear

Measure the thickness of the ears of each shift fork, and measure the width of the shift fork groove on gears D3 & D4, O5, and O6. If the thickness of a shift fork finger is under the service limit, the shift fork must be replaced. If a gear shift fork groove is worn over the service limit, the gear must be replaced.

Shift fork guide pin, shift drum groove wear

Measure the diameter of each shift fork guide pin, and measure the width of each shift drum groove. Replace any shift fork on which the guide pin has worn past the service limit. If a shift drum groove is worn past the service limit, replace the shift drum.

Gear/shaft clearance

Measure the diameter of each shaft with a micrometer, and measure the inside diameter of each gear listed below. Find the difference between the two readings to figure clearance, and replace any gear where clearance exceeds the service limit.

KICKSTARTER

Kickstarter construction is shown in Fig. 418 and its cross section in Fig. 417 . The kick gear is connected to the primary gear on the crankshaft through the idle gear on the output shaft, the idle gear on the drive shaft, and the clutch housing gear. This gear train is free from the drive shaft whenever the clutch is disengaged, thereby allowing the engine to be kicked over even when in gear. This type of starting arrangement is called the primary kick system.

The kick gear ⑩ , constructed with a ratchet on one side, is always meshed with the output shaft idle gear and turns freely anytime the output shaft is turning. The ratchet gear ⑪ , mounted on a splined portion of the kick shaft ③ , always turns with the kick shaft and can be moved sidewise on the shaft. A spring ⑫ presses on the ratchet gear in the direction of the kick gear, but, when the kick pedal ① is not being operated, an arm on the ratchet gear is caught on the guide ⑲ , which prevents the ratchet gear from meshing with the ratchet on the kick gear.

When the kick pedal is operated, the ratchet gear arm is freed from the guide and the ratchet gear then meshes with the kick gear ratchet rotating the kick gear. The gear train of the kick starter system then cranks the engine. As the engine starts, the primary gear through the gear train turns the kick gear. But, since the kick gear rotates in the direction of arrow "A" as shown in Fig. 418 , the kick gear ratchet doesn't catch on the ratchet gear.

When the kick pedal is released, the kick shaft is turned by the return spring returning the kick pedal to its original position. At the same time the ratchet gear arm rides up on the guide, breaking away from the kick gear. The kick gear now turns freely without hindrance.

If the kick pedal return spring weakens or breaks, the kick pedal will not return completely or at all, and the kick gear and ratchet gear will stay partially meshed, making noise while the engine is running. Kick mechanism noise may also result when the kick gear, idle gears, kick shaft, drive shaft, or output shaft becomes worn.

If the ratchet gear or ratchet on the kick gear is worn or damaged, the kick gear will slip, and it will not be possible to kickstart the engine.

Kick gear, shaft wear

Measure the inside diameter of the kick gear, and replace the gear if the diameter is over the service limit. Visually inspect the ratchet portion of the kick gear. If there is any kind of damage, replace the kick gear.

Measure the kick shaft diameter at the kick gear, and replace it if it is under the service limit.

ENGINE LUBRICATION SYSTEM

In the Kawasaki Superlube System, oil is kept in a tank separate from the engine and pumped by an oil pump to the engine where it mixes with the fuel/air mixture from the carburetor. The rate at which the oil is pumped is controlled by both throttle opening and engine speed so that the quantity of oil will vary with

engine need. For normal motorcycle operation, this system, as compared to the system whereby the oil is premixed with the fuel, results in better engine lubrication, which means better engine performance and durability.

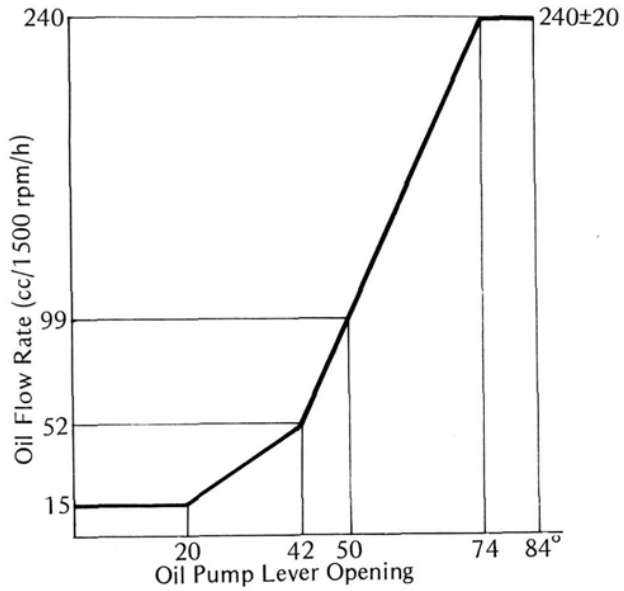
Fig. 420 shows the engine lubrication system. The oil input to the pump is supplied by a hose from the oil tank, and the output from the pump goes through the output hose and then into the non-return check valve at the banjo bolt connection on the right engine cover. The oil pressure, opposing the spring tension on the ball that blocks the valve inlet, causes the oil to flow through the valve and then through the oil pipe that connects to the valve cover where the oil is then ejected through a nozzle into the fuel/air mixture from the carburetor. As this oil and fuel/air mixture reaches the crank chamber, fine droplets of oil lubricate the crankshaft roller bearings and the connecting rod needle bearings and coat the cylinder wall to minimize friction between the wall and piston rings. So that the oil reaches the big end needle bearing, slits and grooves are provided in the connecting rod big end.

Oil Pump

The oil pump for the engine lubrication system is a plunger type. It supplies oil to lubricate the cylinder, piston, and crank chamber parts by pumping oil from the oil tank to the fuel/air mixture being drawn into the engine from the carburetor. In this type of system the oil pump output is controlled to regulate the ratio of oil to fuel/air mixture so that proper lubrication is achieved at all engine speeds and loads.

The oil pump output is controlled partially by the number of plunger strokes. The number of plunger strokes is determined by the speed of oil pump gear rotation. Since crankshaft rotation is transmitted through the primary gear, clutch housing gear, drive shaft idle gear, and output shaft idle gear to the oil pump gears, the oil pump output changes in direct proportion to engine rpm.

Oil Flow Rate (421)



The other factor that controls oil pump output is the plunger stroke length. This length is determined by the oil pump cam position, which is controlled by the throttle grip through the throttle grip and oil pump cables. As the cam is turned by its cable, the plunger stroke increases. A greater plunger stroke will pump more oil. As shown in Fig. 421 , the cam turns increasing the oil pump output from minimum to maximum between 35 ~ 80° of oil pump lever opening.

Pump operation and the path for oil flow through the pump are shown in Fig. 422 . The pump shaft has a worm gear at one end, which meshes with the notches in the plunger. A spring pushes the plunger follower and plunger so that the plunger cam face rests against the camshaft. As the plunger turns, the cam on its face causes it to move back and forth according to the height of the cam. One back and forth movement, in which the plunger makes one complete rotation, makes up one cycle.

Oil flows into **A**, the oil pump inlet, and then in the inlet passage. As the plunger moves in the direction of the camshaft, a chamber **E** is formed between the plunger follower and the cylinder wall. At this time, the plunger follower is turned so that passage **C** in the plunger follower is aligned with the inlet hole in the valve sleeve, and oil flows from the inlet passage through passage **C**, through space **D**, and into the vacuum in chamber **E**. When the plunger moves back in the other direction on the pumping stroke, chamber **E** becomes gradually smaller. This time, however, the plunger follower rotates so that passage **C** is no longer aligned with the inlet hole in the valve sleeve. Instead, passage **C** is aligned with the valve sleeve outlet hole, and the oil forced from chamber **E** flows through passage **C**, through the valve sleeve outlet hole, and into **B**, the oil pump outlet.

The oil pump is designed so that, at zero throttle when the pump is functioning properly, the oil pump lever lower mark aligns with the mark on the lever stopper, and both the oil pump output that is dependent on the length of the plunger stroke and the throttle valve opening are at their minimum. From this base position the pump lever and the throttle valve move at the same rate as the throttle opens. Any disturbance in this relationship will make the oil pump output too high or too low in relation to the throttle valve opening, resulting in poor performance and spark plug trouble from over-lubrication or piston seizure from under-lubrication.

Pump malfunction is generally caused by a deteriorated or damaged **O** ring or oil seal since the other oil pump parts, being well lubricated by the oil passing through the pump, wear very little and seldom become damaged. A defective part reduces oil pump performance, resulting in under-lubrication. Also, air trapped in an oil hose or the pump itself or a clogged check valve obstructs the flow of oil and results in under-lubrication.

Any good quality 2 stroke engine oil that is recommended for air cooled engines may be used for the Superlube System. Any other type of oil, such as ordinary motor oil or transmission oil, is not acceptable as a substitute for the proper oil. Poor quality or the wrong type of oil may cause serious engine damage.

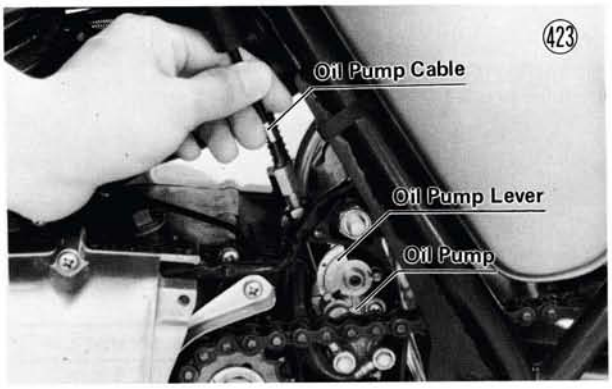
Bleeding the oil pump

When either of the oil pump hoses has been removed, air may become trapped inside, which will obstruct oil flow. See that oil flows from the intake hose before reconnecting it to the pump. Bleed the air from the output hose by idling the engine (below 2,000 rpm) while pulling up on the oil pump cable as shown in Fig. 423 in order to maximize the plunger stroke. Keep the engine idling until the air is completely pumped out. If air bubbles continue to appear in the output hose, check the oil hose connections at the pump.



Oil pump performance test

If a drop in oil pump performance is suspected, check the rate that the oil is being pumped.

- Remove the engine sprocket cover and the oil pump cover.
- Remove the muffler (Pg. 30).
- Detach the banjo bolt from the right engine cover, and run the output hose into a container.
- Install the muffler (Pg. 30).
- **USE A 20:1 MIXTURE OF GASOLINE TO OIL IN THE FUEL TANK IN PLACE OF THE GASOLINE NORMALLY USED.**
- Start the engine, and keep it at 2,000 rpm.
- Pulling up on the oil pump cable, collect the oil that is being pumped for 3 minutes. If the quantity of oil collected corresponds with the table, the oil pump is operating properly.

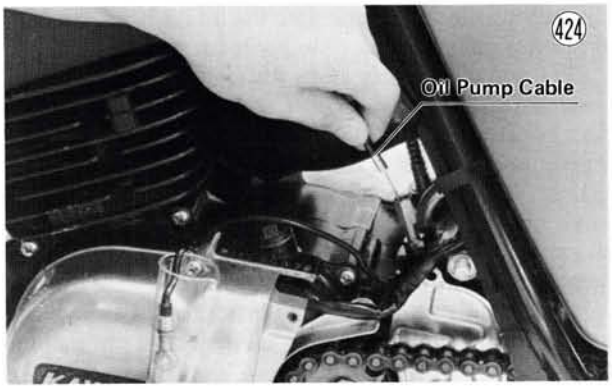


Table 36 Oil Pump Output

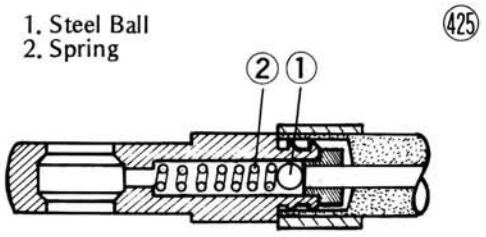
Output/3 minutes @2,000 rpm
3.1~3.7 cc (0.105~0.125 US fl oz)

- If the oil pump output is subnormal, disassemble the pump, inspect the **O** rings and oil seal, and replace if defective. If the trouble is with parts other than the **O** rings or oil seal, replace the oil pump as an assembly. The pump is precision made with no allowance for replacement of individual parts.
- Remove the muffler, and replace the banjo bolt.
- Install the muffler, and replace the oil pump cover and engine sprocket cover.

Check valve

If oil will not pass through the check valve, clean the valve out by using a high flash-point solvent in a squirt can or syringe. Do not use compressed air on the valve since doing so would damage the valve spring. If the check valve does not work properly after being cleaned out, either allowing oil to pass in both directions or not allowing oil to pass at all, replace the check valve.

Check Valve



ROTARY VALVE

The rotary valve consists of a rotary disc, valve cover, oil seal, large and small **O** ring, dowel pin, and sleeve. The rotary disc, made of steel, rotates with the crankshaft by virtue of the dowel pin, fitted in a hole in the crankshaft. The disc is constructed so that as the cutaway portion passes by the intake port in the crankcase, the fuel/air mixture from the carburetor is drawn into the crank chamber below the piston. After the cutaway portion has gone past the intake port, the fuel/air mixture to the crank chamber is cut off.

The disc slides freely along the crankshaft in the small space between the valve cover and crankcase so that the disc, when the cutaway does not coincide with the intake port, forms a tight seal. It is forced tightly against the crankcase or against the intake port in the valve cover, depending on the pressure in the crank chamber. For example, when the crank chamber is pressurized during the downstroke of the piston, the disc is forced tightly against the intake port in the valve cover by the gas pressure, preventing gas blowback through the carburetor.

This method of drawing in the fuel/air mixture through a port at the side of the crankcase is called the rotary valve system. It contrasts with the method whereby an intake port in the cylinder is opened and closed by the piston as it moves up and down inside the cylinder. The rotary valve system is not dependent on the piston for port timing, in which the timing is symmetrical to BDC. Instead, the timing can be determined freely for higher intake efficiency and elimination of gas blowback.

Table 37 Rotary Valve Timing

Intake Open	Intake Close
BTDC 115°	ATDC 55°

An oil seal and 2 **O** rings in the valve seal off the crank chamber from the area inside the right engine cover. A damaged oil seal or **O** ring thereby results not only in fuel/air mixture leaks, but also in transmission oil being drawn into the combustion chamber. This excess oil adversely affects engine performance the same as though the oil pump were pumping too much oil. Also, as this leakage continues, the transmission may seize from insufficient oil.

Whenever the engine is running, the rotary disc and the inner surface of the valve cover wear against each other. As this wear progresses and the side to side motion of the disc on the shaft increases, and the disc may possibly warp.

Oil seal, O ring damage

Visually inspect the oil seal and the **O** rings. If the lip of the oil seal is deformed, hardened, discolored, or otherwise damaged, replace the oil seal. An **O** ring should be replaced if damaged.

Rotary disc warp, wear

Visually inspect the rotary disc. If the rotary disc has become warped, replace it.

Measure the thickness of the rotary disc. Replace it if it has worn past the service limit.

ENGINE BEARINGS AND OIL SEAL

The engine bearings and oil seals are listed in Tables 40 and 41. Worn or damaged bearings cause engine noise, power loss, and vibration, adversely affect engine and transmission parts, and shorten engine life. The crankshaft oil seals serve to seal the crank chamber, and if damaged will permit leaks to the crank chamber, causing a loss of power. Also, the crankshaft oil seal in the rotary valve cover forms a seal between the crank chamber and the transmission part of the crankcase, and if damaged will allow oil to be drawn into the crank chamber, causing running problems from an oil rich mixture. Any damaged, hardened, or otherwise defective oil seal will allow oil to leak.

Roller bearing wear, damage

Since the roller bearings are made to extremely close tolerances, the clearance cannot normally be measured. Therefore, the condition of the bearings must be judged by feel. Wash each bearing with a high flash-point solvent, dry it (**do not spin it while it is dry**), and oil it. Spin it by hand to check its condition. If it is noisy, does not spin smoothly, or has any rough spots, it must be replaced. Before reinstalling the bearing, replace its oil seal with a new one. Press in the bearing so that its face is level with that of the crankcase.

Needle bearing wear, damage

The rollers in the needle bearings wear so little that the wear is difficult to measure. Instead, inspect the bearings for abrasions, color change, or other damage. If there is any doubt as to the condition of either bearing, replace it.

Oil seal damage

Inspect the oil seals, and replace any if the lips are misshapen, discolored (indicating the rubber has deteriorated), hardened, or otherwise damaged. Since an oil seal is nearly always damaged on removal, any removed oil seals must be replaced. When pressing in an oil seal which is marked, press it in with the mark facing out. Press it in until the oil seal stops.

FUEL TANK

The fuel tank capacity of 1974~1975 models is 7.4 liters (2.0 US gal), 1 liter (¼ US gal) of which forms the reserve supply. For 1976 and later models, the fuel tank capacity is 6.7 liters (1.8 US gal), 1.1 liters (0.3 US gal) of which forms reserve supply. A cap is attached to the top of the tank, and a fuel tap to the bottom at one side. Air vents are provided in the cap so that when the tap is turned on, low pressure, which would hinder or prevent fuel flow to the carburetor, will not develop in the tank.

Fuel tap construction is shown in Fig. 428 . The fuel tap has three positions: off, on, and reserve. With the tap in the off position, no fuel will flow through the tap; with the tap in the on position, fuel flows through the tap by way of the main pipe until only the reserve supply is left in the tank; with the tap in the reserve position, fuel flows through the tap from the bottom of the tank. The fuel tap contains a strainer and a sediment cup to filter out dirt and collect water.

Inspection and cleaning

If fuel leaks from the cap or from around the fuel tap, the **O** ring or gasket may be damaged. Visually inspect these parts, and replace if necessary.

Examine the air vents in the cap to see if any are obstructed. Use compressed air to clear any obstructed vents.

Periodically inspect and clean the fuel tap strainer and the sediment cup, using a high flash-point solvent and a fine brush on the strainer. If the strainer is damaged, it must be replaced. If the sediment cup contains much water or dirt, the fuel tank and the carburetor may also need to be cleaned.

To clean out the fuel tank, disconnect the fuel hose, remove the fuel tap, and flush out the tank with a high flash-point solvent. To clean out the carburetor float bowl, remove the carburetor (Pg. 34), and remove the four screws to take off the bowl. Drain the fuel, and clean out any sediment.

WHEELS

Wheel construction is shown in Fig. 429 and 430. The following sections Pgs. 118~124 cover the tire, rim and spokes, axle, grease seals, wheel bearings, and brakes.

TIRES

The tires are designed to provide good traction and power transmission during acceleration and braking even under bad surface conditions when they are inflated to the correct pressure and not overloaded. The maximum recommended load in addition to vehicle weight is 150 kg (330 lbs).

If the tires are inflated to too high a pressure, riding becomes rough, the center portion of the tread wears quickly, and the tires are easily damaged.

If inflation pressure is too low, the shoulder portions wear quickly, the cord suffers damage, fuel consumption is high, and handling is poor. In addition, heat builds up at high speeds, and tire life is greatly shortened.

To ensure safe handling and stability, use only the recommended standard tires for replacement, inflating them to the standard pressure. However, a certain variation from the standard pressure may be desired depending on road surface conditions (rain, ice, rough surface, etc.).

			97.5~150 kg (215~330 lbs) load	2.0 kg/cm² (28 psi)

A bead protector is provided on the rear wheel to keep the tire from slipping on the rim and damaging the valve stem when the brakes are heavily applied.

Tire wear, damage

Tires must not be used until they are bald, or if they are cut or otherwise damaged. As the tire tread wears down, the tire becomes more susceptible to puncture and failure. 90% of tire failures occur during the last 10% of tire life.

RIM AND SPOKES

The rim of each wheel is made of steel and is connected to the hub by the spokes. A rim band around the outside center of the rim keeps the tube from coming into direct contact with the rim and the spoke nipples.

The spokes are connected to the hub at a tangent and in different directions so that different spokes bear the brunt of the load during different conditions. With the spokes doing specialized work, the strength of the spokes can be used more effectively.

When the motorcycle is at rest (Fig. 432 A), the spokes above the axle are stretched and tense, while the spokes below the axle are slightly loose and do not provide support. During acceleration (B), the spokes running to the hub in the direction of rotation are stretched, while during deceleration or braking (C), the spokes running to the hub opposite to the direction of rotation are the ones that are stretched. In both cases B and C, the spokes that are not stretched (omitted from the diagram) are slightly loose and do not provide support. A damping action to the shock from the ground is achieved by flexing of the spokes since they are arranged in this cross pattern instead of running straight from the hub to the rim.

Since the spokes must withstand this repeated stress, it is important to take sufficient care that the spokes are not allowed to loosen and that they are tightened evenly. Loose or unevenly tightened spokes cause the rim to warp, increase the possibility of spoke breakage, and hasten nipple and spoke metal fatigue.

		#9-#10x167.5 (Left)	#9-#10x166.6 (Left)

NOTE: The rim size in Table 44 is outer width by diameter, both in inches. The "W" means that the rim is welded. The spoke size is diameter number by length in millimeters. The two numbers for diameter size mean that each spoke has two diameters. To make the spoke more resistant to breakage, the diameter is greater near the hub.

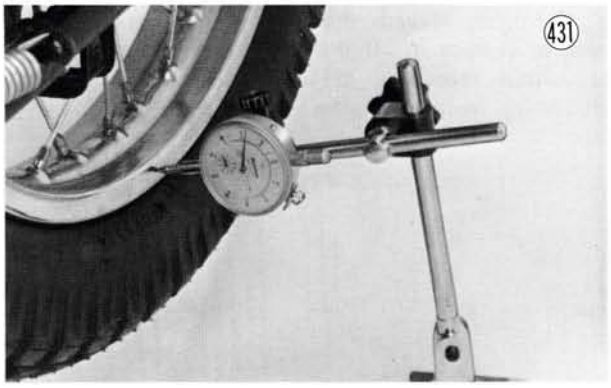
Spoke breakage

If any spoke breaks, it should be replaced immediately. A missing spoke places an additional load on the other spokes, which will eventually cause other spokes to break.

Periodically check that all the spokes are tightened evenly since they stretch a certain amount during use. Standard spoke tightening torque is 20~40 kg-cm (17 ~ 35 in-lbs). Over or under tightening may cause breakage.

Rim runout

Set a dial gauge to the side of the rim, and rotate the wheel to measure axial runout. The difference between the highest and lowest dial reading is the amount of runout.



Set the dial gauge to the inner circumference of the rim, and rotate the wheel to measure radial runout. The difference between the highest and lowest dial reading is the amount of runout.

Spoke Force

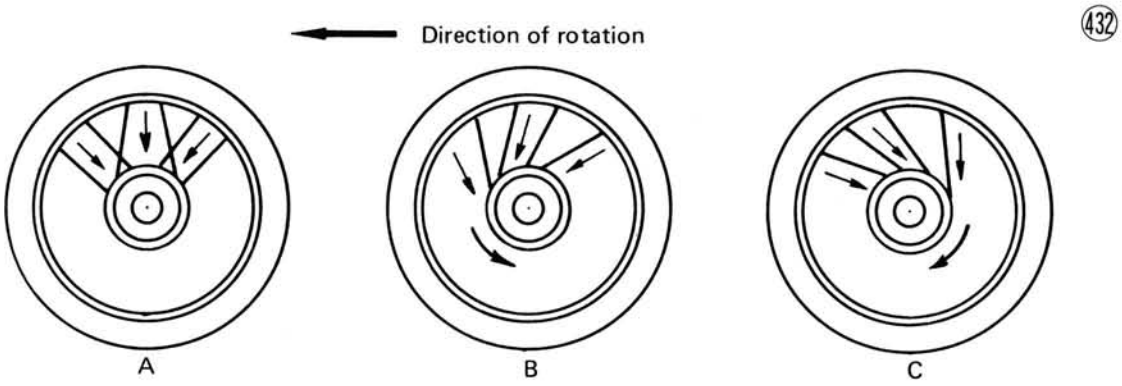


Table 45 Rim Runout

	Standard	Service Limit
Axial	under 0.8 mm (under 0.03 in)	3 mm (0.12 in)
Radial	under 1.0 mm (under 0.04 in)	2.0 mm (0.08 in)

A certain amount of rim warp (runout) can be corrected by recentering the rim, that is, loosen some spokes and tighten others to change the position of different parts of the rim. If the rim is badly bent, however, it should be replaced.

AXLE

A bent axle causes vibration, poor handling, and instability.

To measure axle runout, remove the axle, place it in V blocks that are 100 mm (4.0 in) apart, and set a dial gauge to the axle at a point halfway between the blocks. Turn the axle to measure the runout. The amount of runout is the amount of dial variation.

If runout exceeds the service limit, straighten the axle or replace it. If the axle cannot be straightened to within tolerance, or if runout exceeds 0.7 mm (0.028 in), replace the axle.

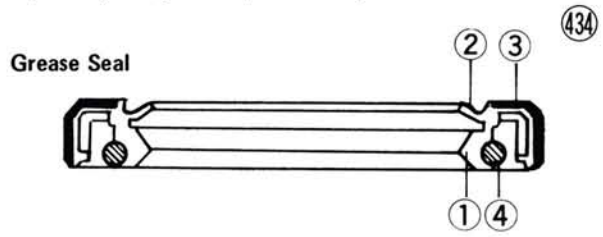
GREASE SEALS AND WHEEL BEARINGS

A grease seal is fitted in both sides of the front hub and in the left side of the rear hub. Each grease seal is a rubber ring equipped with a steel band on its outer circumference. The grease seal inner rib is held against the axle collar by a wire spring band. Since the grease seal not only seals in the wheel bearing grease but also keeps dirt and moisture from entering the hub, the use of a damaged grease seal will cause the wheel bearing to wear quickly. A grease seal is also fitted in the front brake panel to keep speedometer gear and bearing grease from getting on the brake linings. Also, this grease seal prevents the minute particles from the brake linings from reaching the speedometer gear and wheel bearings.

A wheel bearing is fitted in both sides of each hub. Since worn wheel bearings will cause play in the wheel, vibration, and instability, they should be cleaned, inspected, and greased periodically.



1. Primary Lip
2. Secondary Lip
3. Metal Band
4. Wire Spring Band

Inspection and lubrication

If the grease seals are examined without removing the seals themselves, look for discoloration (indicating the rubber has deteriorated), hardening, damage to the internal ribbing, or other damage. If the seal or internal ribbing has hardened, the clearance between the seal and the axle sleeve will not be taken up, which will allow dirt and moisture to enter and reach the bearing. Whenever in doubt as to its condition and whenever the seal is removed for greasing the bearing, the seal should be replaced. The seals are generally damaged upon removal.

Since the wheel bearings are made to extremely close tolerances, the clearance cannot normally be measured. Wash the bearing with a high flash-point solvent, dry it (do not spin it while it is dry), and oil it. Spin it by hand to check its condition. If it is noisy, does not spin smoothly, or has any rough spots, it must be replaced. If the same bearing is to be used again, re-wash it with a high flash-point solvent, dry it, and pack it with good quality bearing grease before installation. Turn the bearing around by hand a few times to make sure the

grease is distributed uniformly inside the bearing, and wipe the old grease out of the hub before bearing installation. Clean and grease the wheel bearings and the front hub gear box (speedometer gear) in accordance with the Periodic Maintenance Chart (Pg. 152).

BRAKES

The front and rear wheels are both equipped with a leading-trailing type of drum brake. "Leading-trailing" means that one of the two brake shoes leads, expanding against the drum in the direction of drum rotation, and the other shoe trails, expanding in the direction opposite drum rotation.

On both the front and rear brakes, the force applied by the rider upon braking is transmitted into the interior of the brake by a camshaft. The force applied at the brake lever or pedal is transmitted by a cable to the cam lever which then turns the camshaft. When the camshaft rotates, the large portion of the cam is forced between the two brake shoes. Since the shoes are only held together away from the drum by springs, the cam, overcoming spring tension, pushes the shoes outward against the drum. The leading shoe rotates in direction "A", and the trailing shoe in direction "B" as shown in the diagram.

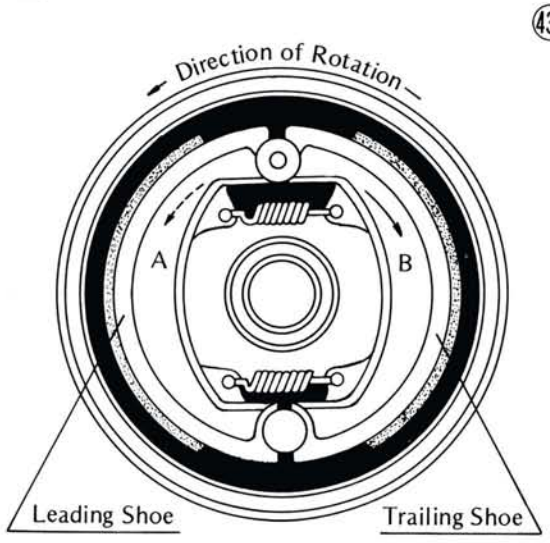
The friction between the linings and the drum, which decelerates the motorcycle, gradually wears down the brake shoe linings. On the outside of each brake panel is a brake lining wear indicator which, as the brake is applied, moves in direct proportion to the distance that the brake shoe linings move to reach the brake drum. As the linings wear down, the lining surface has farther to travel before reaching the drum. The indicator accordingly travels farther until it finally reaches the end of usable range when the lining wear has reached the service limit.

Due to wear of the brake drum, shoe linings, and cam, periodic brake adjustment is required. However, if the brake parts become overworn, adjustment will not be sufficient to ensure safe brake operation. Not only can overworn parts crack (drum) and otherwise suffer damage as they lose their braking effectiveness, but, if the cam wears to the point where it turns nearly horizontal when the brake is fully applied, the brake may lock in the operated position, or brake lever or pedal return may be very sluggish. All brake parts should be checked for wear in accordance with the Periodic Maintenance Chart (Pg. 152).

WARNING:Brake linings contain asbestos fiber. Inhalation of asbestos may cause serious scarring of the lungs and may promote other internal injury and illness, including cancer. Observe the following precautions when handling brake linings:

1. **Never blow brake lining dust with compressed air.**
2. **If any components are to be cleaned, wash with detergent, then immediately discard the cleaning solution and wash your hands.**
3. **Do not grind any brake lining material unless a ventilation hood is available and properly used.**

Brake



Brake drum wear

Measure the inside diameter of the brake drum with calipers to determine wear. Since uneven drum wear will decrease braking effectiveness, take measurements at a minimum of two places. If the drum is worn unevenly or if it is scored, turn the drum down on a brake drum lathe or replace the hub. (Do not turn it down to the service limit, and do not turn it down if any diameter measurement exceeds the service limit.) If any diameter measurement exceeds the service limit, replace the hub with a new one.

Table 48 Brake Drum Inside Diameter

	Standard	Service Limit
Front	120.000~120.140 mm (4.724~4.730 in)	120.75 mm (4.75 in)
Rear	130.000~130.160 mm (5.118~5.124 in)	130.75 mm (5.15 in)

Brake shoe lining wear

Check the thickness of the brake linings, and replace both shoes as a set if the thickness at any point is less than the service limit. If the thickness of the brake linings is sufficient, check the linings for uneven wear, and file or sand down any high spots. With a wire brush, remove any foreign particles imbedded in the lining surface. Wash off any oil or grease with a high flash-point solvent. In case the linings are damaged or the surface cannot be restored by sanding and cleaning, the shoes must be replaced.

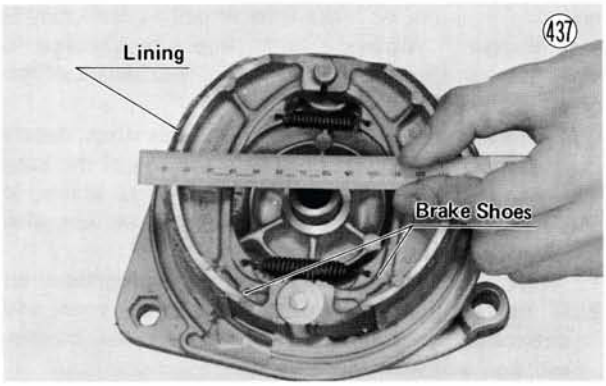


Table 49 Brake Lining Thickness

Brake shoe spring tension

If the brake springs become stretched, they will not pull the shoes back away from the drum after the brake lever or pedal is released, causing the shoes to drag on the drum. Remove the springs, and check their free length with vernier calipers. If either is stretched beyond the service limit, replace both springs.

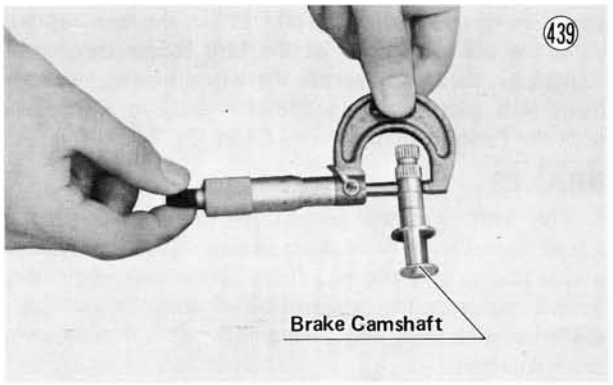
Long Spring	44.5~45.5 mm (1.752~1.791 in)	48 mm (1.89 in)

Camshaft, shaft hole wear

Excessive shaft to hole clearance will increase camshaft play and reduce braking efficiency.

Measure the shaft diameter with a micrometer, and replace it if it is worn down to less than the service limit.

Measure the inside diameter of the camshaft hole, and replace the brake panel if the hole is worn past the service limit.



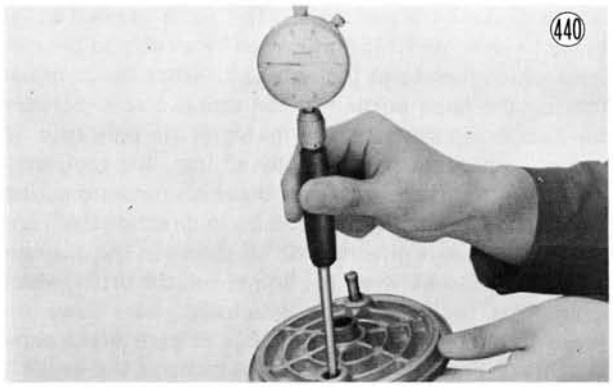


Table 51 Brake Camshaft, Hole Diameter

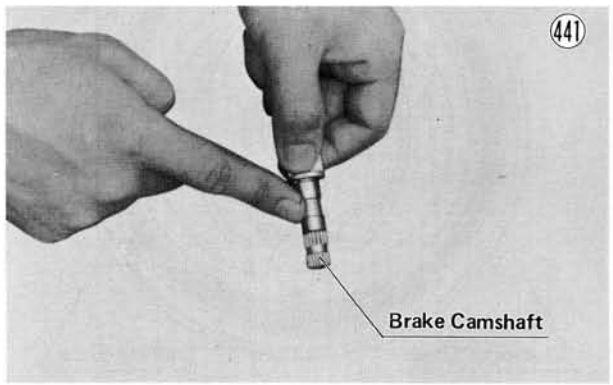
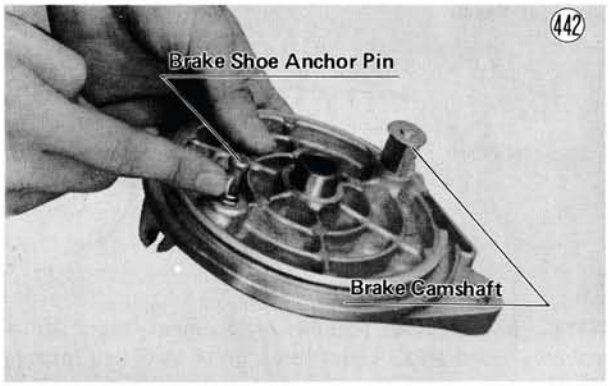
	Standard	Service Limit
Camshaft	11.957~11.984 mm (0.4707~0.4718 in)	11.83 mm (0.466 in)
Shaft Hole	12.000~12.027 mm (0.4724~0.4735 in)	12.18 mm (0.480 in)

Lubrication

Every time that the brakes are disassembled, and in accordance with the Periodic Maintenance Chart (Pg. 152), wipe out the old grease, and re-grease the brake pivot points. Apply grease to the brake shoe anchor pins, spring ends, and cam surface of the camshaft, and fill the camshaft groove with grease. Do not get any grease on the brake shoe linings, and wipe off any excess grease so that it will not get on the linings or drum after brake assembly.

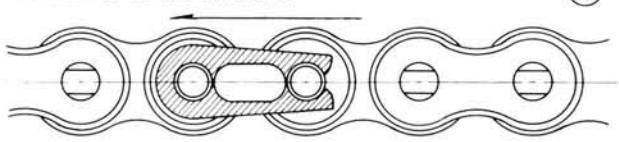




DRIVE CHAIN

The drive chain used to transmit the engine power to the rear wheel is the Enuma EK428 SH-G 118 link chain. This chain is provided with a master link to facilitate removal and replacement. To minimize any chance of the master link dislodging, the master link is fitted with the closed end of the "U" pointed in the direction of chain rotation. See Fig. 443

Direction of Chain Rotation



Chain construction is shown in Fig. 445 . Most chain wear occurs between the pins and bushings, and between the bushings and rollers, rather than on the outside of the rollers. This wear causes the chain to lengthen. If the chain is left unadjusted, the lengthening will lead to noise, excessive wear, breakage, and disengagement from the sprockets. If the chain is allowed to wear too much, the distance from roller to roller is so much greater than the distance between each tooth of the sprocket that the wear rapidly accelerates.

The rate of wear can be greatly reduced, however, by frequent and adequate lubrication, especially between the side plates of the links so that oil can reach the pins and bushings inside the rollers.

Wear

When the chain has worn so much that it is more than 2% longer than when new, it is no longer safe for use and should be replaced. Whenever the chain is replaced, inspect both the engine and rear sprockets, **and replace them if necessary. Overworn sprockets will cause a new chain to wear quickly.**

Since it is impractical to measure the entire length of the chain, determine the degree of wear by measuring a 20 link length of the chain. Stretch the chain taut either by using the chain adjuster, or by hanging a 10 kg (20 lb) weight on the chain. Measure the length of 20 links on a straight part of the chain from pin center of the 1st pin to pin center of the 21st pin. If the length is greater than the service limit, the chain should be replaced.

NOTE: The drive system was designed for use with the **Enuma EK428 SH-G 118-link chain. For maximum strength and safety, the Enuma EK428 SH-G 118-link** chain must be used for replacement.

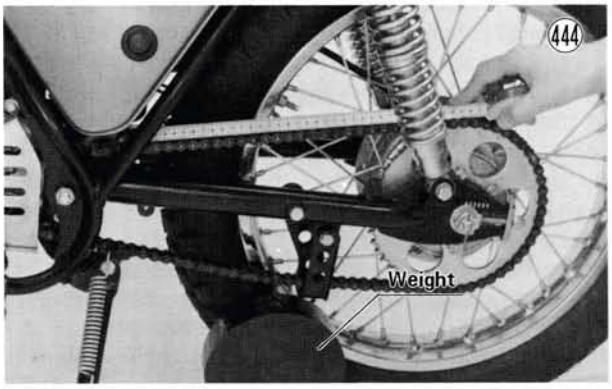


Table 52 Drive Chain 20-link Length

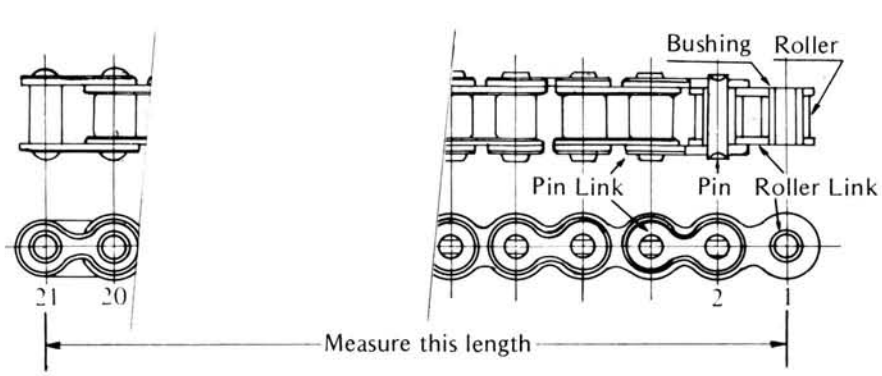
Standard	Service Limit
254.0~254.5 mm (10.00~10.02 in)	259 mm (10.2 in)

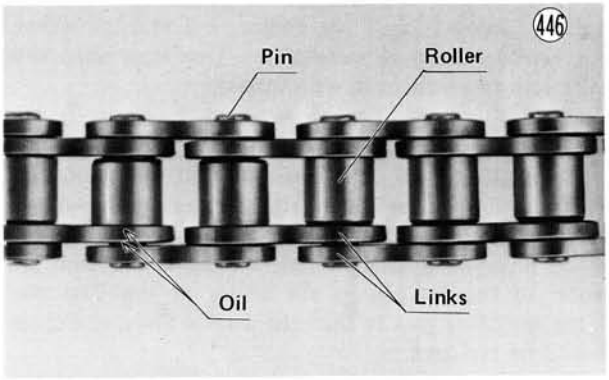
Lubrication

In order for the chain to function safely and wear **slowly, it should be properly lubricated in accordance with the Periodic Maintenance Chart (Pg. 152). Lubrication is also necessary after riding through rain or on wet roads, or any time that the chain appears dry. Any-**

Drive Chain



time that the motorcycle including the chain has been washed, the chain should be adequately lubricated on th spot in order to avoid rust.



446

The chain should be lubricated with a lubricant which will both prevent the exterior from rusting and also absorb shock and reduce friction in the interior of the chain. An effective, good quality lubricant specially formulated for chains is best for regular chain lubrication. If a special lubricant is not available, a heavy oil such as SAE 90 is preferred to a lighter oil because it will stay on the chain longer and provide better lubrication. Apply the oil to the sides of the rollers and between the side plates of the links so that oil will penetrate to the pins and bushings where most wear takes place. Wipe off any excess oil.

Dirt will cling to the oil and act as an abrasive, accelerating chain wear. Whenever the chain becomes particularly dirty, it must be cleaned in kerosene and then soaked in a heavy oil. Shake the chain while it is in the oil so that oil will penetrate to the inside of the rollers. Better oil penetration to the interior is achieved by boiling the chain in grease, but care must be taken not to overheat the grease.

SPROCKETS

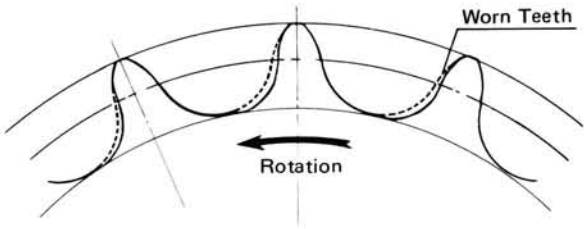
There are two sprockets for the drive chain. A forward sprocket, or engine sprocket, is mounted on the end of the output shaft and is used to drive the chain. A rear sprocket is connected to the rear wheel hub through the rear wheel coupling and is driven by the chain to turn the rear wheel.

Sprockets that have become excessively worn cause noise with the chain and greatly accelerate chain and sprocket wear. The sprockets should be checked for wear any time that the chain is replaced. A warped rear sprocket destroys chain alignment such that the chain may break or jump from the sprockets when traveling at high speed. The sprockets should be checked for wear and the rear sprocket for warp any time that the chain is replaced.

Sprocket wear

Visually inspect the sprocket teeth. If they are worn as illustrated, replace the sprocket.

Sprocket Teeth



447

NOTE: If a sprocket requires replacement, the chain is probably worn also. Upon replacing a sprocket, inspect the chain.

Measure the diameter of the sprocket at the base of the teeth. If the sprocket is worn down to less than the service limit, replace the sprocket.

Rear sprocket warp

Elevate the rear wheel so that it will turn freely, and set a dial gauge against the rear sprocket near the teeth as shown in Fig. 449. Rotate the rear wheel. The difference between the highest and lowest dial gauge readings is the amount of runout (warp).

If the runout exceeds the service limit, replace the rear sprocket.

REAR WHEEL COUPLING

The rear wheel coupling connects the rear sprocket to the wheel. The forces that are transmitted between the rear sprocket and the rear hub are transmitted through rubber shock dampers in the coupling to absorb some of the shock resulting from sudden changes in torque due to acceleration or braking.

Damper inspection

Remove the rear wheel coupling (Pg. 69), and inspect the rubber dampers.

Replace the dampers if any appear damaged or deteriorated.

STEERING STEM

The steering stem supports the handlebar, front fork shock absorbers, and front fender, and turns inside the frame head pipe. Ball bearings in the upper and lower ends of the head pipe enable the steering stem to turn smoothly and easily.

The steering stem itself does not wear, but it may become bent. If it becomes bent, the steering will be stiff, and the bearings may become damaged.

The steering stem will require periodic adjustment as it becomes loose due to bearing wear. Overtightening during adjustment, however, will make the steering stiff and cause accelerated bearing wear. Lack of proper lubrication will also bring about the same results.

From overtightening or from a heavy shock to the steering stem, the bearing race surfaces may become dented. Damaged bearing races will cause the handlebar to jerk or catch when turned.

Steering stem warp

Examine the steering stem, and replace it if it is bent.

Bearing wear, damage

Wipe the bearings clean of grease and dirt, and examine the races and balls. If the balls or races are worn, or if either race is dented, replace both races and all the balls for that bearing as a set.

Bearing lubrication

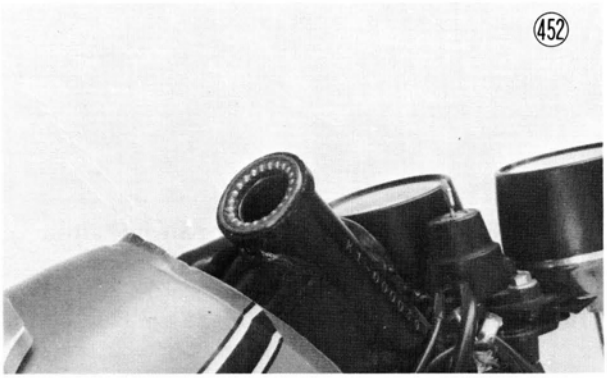
In accordance with the Periodic Maintenance Chart (Pg. 152), and whenever the steering stem is disassembled, the steering stem bearings should be relubricated.

Wipe all the old grease off the races and balls, washing them in a high flash-point solvent if necessary. Replace the bearing parts if they show wear or damage. Apply grease liberally to the upper and lower races, and stick the bearing balls in place with grease.

Grease seal deterioration, damage

Inspect the grease seal for any signs of deterioration or damage, and replace it if necessary.

Replace the grease seal with a new one whenever it has been removed. The grease seal comes off whenever the lower bearing inner race is removed.



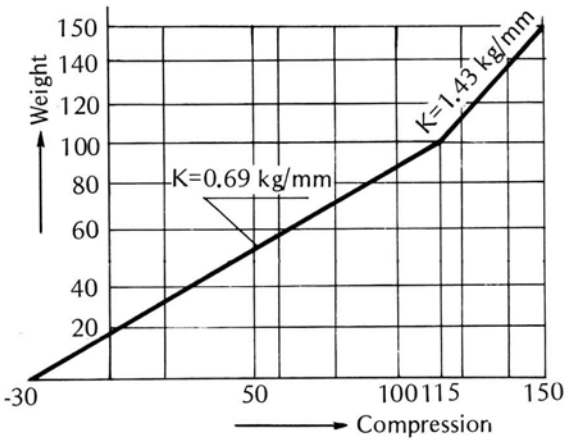
452

FRONT FORK

Front fork construction is shown in Fig. 454 . It consists of two shock absorbers connected to the frame head pipe by the stem base and stem head bracket. It accomplishes shock absorption through spring action, air compression in the inner tube, and resistance to the flow of the oil forced into the cylinder by tube movement.

Front Spring Force

453



Each shock absorber is a telescopic tube including an inner tube ⑪ , outer tube ⑮ , cylinder ㉒ , piston ⑯ , collar ㉑ , and cylinder base ㉓ . The inner tube fits into the outer tube, altering its position in the outer tube as the tube arrangement absorbs shocks. The cylinder is fixed to the bottom of the outer tube and the piston (equipped with a piston ring ⑰) is secured to the top of the cylinder. The collar (coupled with a non-return valve ⑳), fixed in the lower end of the inner tube, forms the upper part of the lower chamber and together with the piston helps seal the upper chamber. The collar and cylinder base configuration functions to form an oil lock at the end of the compression stroke to prevent the inner tube from striking the bottom. Vertically arranged orifices (3) in the upper part of the cylinder bring about an oil lock at the end of the extension stroke to prevent the inner tube from striking the top.

Oil is prevented from leaking out by the oil seal ⑭ , which is fitted at the upper end of the outer tube. A dust seal ⑫ on the outside of the tube keeps dirt and water from entering and damaging the oil seal and tube surface.

Compression stroke

Whenever a load is placed on the front fork and whenever the front wheel receives a shock, the inner tube ⑤ moves down inside the outer tube ④ , compressing both the spring ① and the air in the inner tube. At the same time, low pressure (suction) is created in an enlarging chamber (upper chamber) formed between the inner tube and the cylinder ⑩ , and draws in oil from a diminishing chamber (lower chamber) formed between the outer tube and the cylinder. As the lower chamber shrinks in size with oil passing freely through the non-return valve ⑧ into the upper chamber, oil also passes freely through the cylinder lower orifices into the cylinder as the inner tube approaches the cylinder base

⑪. Near the end of the compression stroke, the clearance between the tapered-out cylinder base and the collar at the lower end of the inner tube approaches zero. The resulting resistance to the flow of oil through this small space slows the downward movement, finally forming an oil lock to finish the compression stroke.

Extension stroke

Following the compression stroke is the extension stroke, in which the inner tube is pushed back out by the compressed spring. As the tubes move apart, the upper chamber grows smaller, forcing the oil through the cylinder upper orifices since the oil cannot return the way it came through the non-return valve. These small holes resist the oil flow into the inner tube, damping fork extension. Near the end of the extension stroke both the cylinder spring and the arrangement of the cylinder upper orifices provide further resistance to extension. As the collar rises reducing the size of the upper chamber, the cylinder upper orifices are eliminated as upper chamber outlets one by one. When the last one is eliminated, an oil lock forms, finishing the extension stroke.

Either too much or too little oil in the shock absorbers will adversely affect shock damping. Too much oil or too heavy an oil makes action too stiff; too little oil or too light an oil makes the action soft, decreases damping potential, and may cause noise during fork movement.

Contaminated or deteriorated oil will also affect **shock damping and, in addition, will accelerate internal wear. The fork oil should be changed in accordance with the Periodic Maintenance Chart (Pg. 152).**

A bent, dented, scored, or the otherwise damaged inner tube will damage the oil seal, causing oil leakage. A badly bent inner tube may cause poor handling.

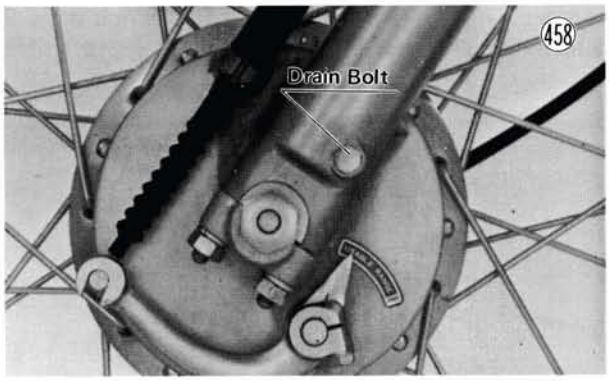
Fork oil

To check the fork oil level, first place a jack or stand under the engine so that the front wheel is raised off the ground. Remove the screw from the top bolt. Insert a rod down into the tube, and measure the distance from the top of the top bolt to the oil level. If the oil is below the correct level, add enough oil to bring it up to the proper level, taking care not to overfill.

Table 56 Fork Oil

Type	Amount per side	Oil level from top of top bolt
SAE 5W20	145~155 cc (4.90~5.24 US fl oz)	385~415 mm (15.2~16.3 in)

To drain out the old oil, remove the drain bolt from the lower end of the outer tube on each side. With the front wheel on the ground, push down on the handlebar a few times to pump out the oil. Replace the drain bolts, remove the top bolt from each side, and pour in the specified type and amount of oil. Then replace the top bolts, tightening them with 1.5~2.0 kg-m (11~14.5 ft-lbs) of torque.



Spring tension

Since the spring becomes shorter as it weakens, check its free length to determine its condition. If the spring of either shock absorber is shorter than the service limit, it must be replaced. If the length of a replacement spring and that of the remaining spring vary greatly, the remaining spring should also be replaced in order to keep the shock absorbers balanced for motorcycle stability.

Inner tube damage

Visually inspect the inner tube, and repair any damage. If the damage is not repairable, replace the inner tube. Since damage to the inner tube damages the oil seal, replace the oil seal whenever the inner tube is repaired or replaced.

REAR SHOCK ABSORBERS

The rear shock absorbers serve to dampen shock transmitted to the frame and rider from the rear wheel. For this purpose they are connected between the frame and the rear end of the swing arm. Shock absorption is performed by the spring and by the resistance to the flow of oil inside each unit. Shock absorption is further aided by the use of rubber bushings in both the upper and lower shock absorber mountings.

Since the rear shock absorbers are sealed units which cannot be disassembled, only external checks of operation are necessary. With the shocks removed, compress each one and see that the compression stroke is smooth and that there is damping besides spring resistance to compression. When the unit is released, the spring should not suddenly snap it to full length. It should extend smoothly with notable damping. When the shock absorber is operated, there should be no oil leakage. If either shock absorber does not perform all of these operations satisfactorily, or if one unit feels weaker than the other, replace both shock absorbers as a set. If only one unit is replaced and the two are not balanced, motorcycle instability at high speeds may result.

Shock absorber spring force for the 5 different settings is shown in the graph.

Bushings

Check the rubber bushings, and replace any that are worn, cracked, hardened, or otherwise damaged.

SWING ARM

The swing arm is designed to work with the shock absorbers to dampen the shock to the frame from the rear wheel. The rear of the swing arm is connected to the frame by the rear shock absorbers, while the front end pivots on a shaft connected to the frame. When the rear wheel receives a shock, the swing arm, pivoting on its shaft, allows the wheel to move up and down in relation to the frame within the limits of the shock absorbers.

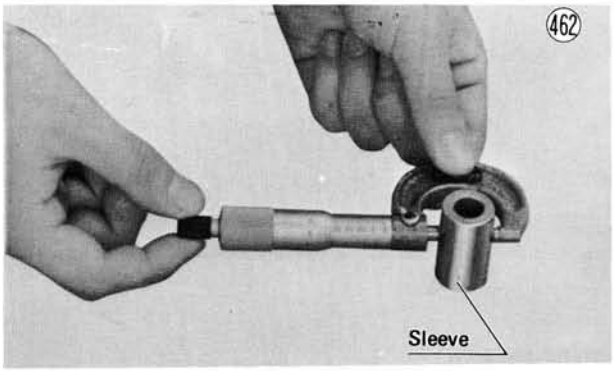
Wear takes place where the short sleeves and bushes rub together. If wear has progressed such that the swing arm has become loose, the motorcycle will be unstable. To minimize wear, the swing arm should be kept properly lubricated.

A bent pivot shaft or twisted swing arm will also cause instability by throwing the rear wheel out of alignment.

Sleeve, bushing wear

Measure the outside diameter of the short sleeves at both ends with a micrometer. Replace a sleeve if the diameter is less than the service limit or if it shows visible damage.



Measure the inside diameter of each bushing with a cylinder gauge. Replace both bushings if the diameter of either exceeds the service limit. Also, replace both bushings if either shows visible damage.

Pivot shaft

To measure the pivot shaft runout, set the pivot shaft on **V** blocks at the ends of the shaft, and set a dial gauge to the shaft halfway between the blocks. Turn the shaft to measure the runout. The amount of runout is the amount of dial variation. If the shaft runout exceeds the service limit, straighten it. If it cannot be straightened, or if the runout exceeds 0.7 mm (0.028 in), replace the shaft.

Pull out the pivot shaft, and remove all old grease. Apply grease liberally to the portion of the sleeves which comes in contact with the bushes.

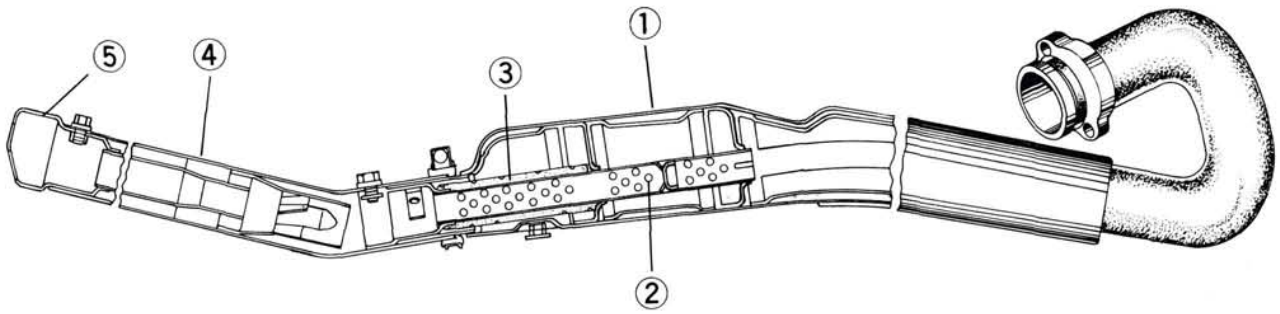
MUFFLER

The muffler reduces exhaust noise and conducts the exhaust gases back away from the rider while keeping power loss to a minimum. If much carbon is built up inside the muffler, exhaust efficiency is reduced, which lowers the engine output power.

To remove built-up carbon, first remove and disassemble the muffler (Pg. 30). Clean the baffle tube with a wire brush and by striking it gently, or by burning the carbon out. Also, examine the glass wool. Remove some of the dirtiest part if it is especially dirty. If it is exceptionally dirty, wash it out in a high flash-point solvent or replace it with new glass wool.

If there is any exhaust leakage where the muffler connects to the cylinder, or if the muffler gasket appears damaged, replace the gasket. If the muffler is badly damaged, dented, cracked, or rusted, replace it.

Muffler



FLYWHEEL MAGNETO

The flywheel magneto, fundamentally a single phase A.C. generator, can be divided up into a moving part called the flywheel, which is taper fitted to one end of the crankshaft, and a stationary part called the stator, which is located inside the flywheel and fixed to one side of the crankcase. The flywheel has 6 permanent magnets riveted and evenly spaced in its circumference and arranged as 3 north-south sets to generate in the stator coils a current with 3 cycles per flywheel revolution. The outer surface of the hub inside the flywheel serves as a cam to control the opening and closing of the contact breaker. The stator has coils wrapped about 3 laminated iron cores in which current is generated for ignition, lighting, and charging. Also, mounted on the stator plate are the contact breaker, which is provided to make the flow of current to the ignition coil primary winding intermittent, and the condenser, which is provided so that the interruption of current at the contact breaker points is a clean electrical break.

The electrical wiring, shown in Fig. 467 , is made up of circuits to provide for ignition, lighting, and charging. Although the current required by these circuits is supplied basically by the flywheel magneto, electrical troubleshooting should be done first with the parts other than the generating components of the magneto. That is, the condition of the flywheel magneto itself should be checked only after the wiring, ignition switch, spark plug, contact breaker points, fuse, rectifier, battery, etc. have been checked. Flywheel magneto testing and further details on its operation are divided up between the section on the ignition system and the section on the lighting/charging system.

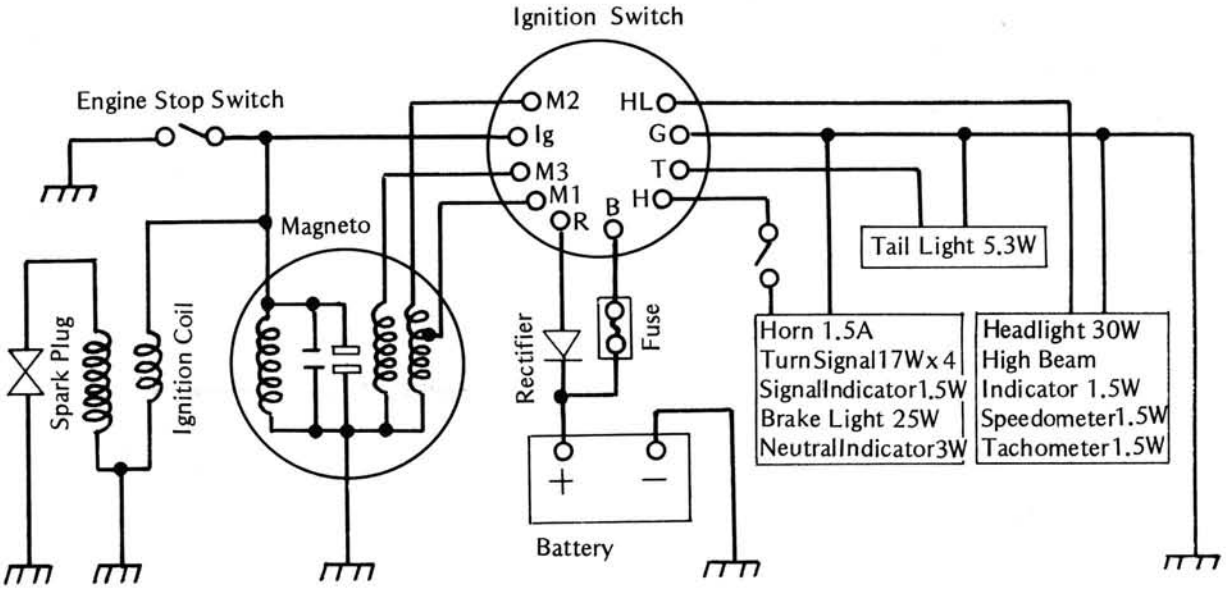
IGNITION SYSTEM

The ignition system, shown in Fig. 468 , consists of the spark plug (Pg. 143), contact breaker, condenser, ignition coil, and ignition magneto coil. The flow of the electrical energy produced in the ignition magneto coil is broken up by the contact breaker and sent as a surge of current or pulse to the ignition coil, which acting as a pulse transformer steps up the voltage such that a spark will jump across the spark plug electrodes. For this system to function properly, all ignition parts must be in good order, the ignition timing correctly set, the ignition and engine stop switches not shorted, all wiring in good condition (no shorts or breaks and no loose or tarnished connections), and the flywheel magnets supplying a satisfactory magnetic field.

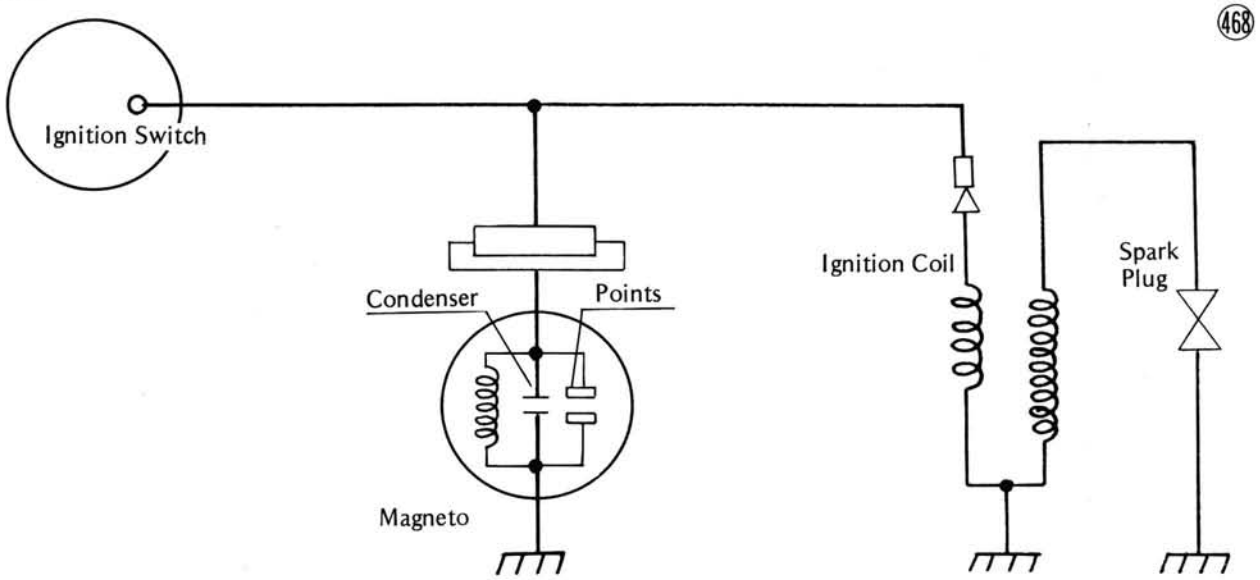
When the flywheel rotates, magnetic flux cutting through the ignition magneto coil induces electric current in the coil. One end of the coil is grounded, while the other end connects both to the ignition coil primary winding and to the contact breaker. When the contact breaker points are closed, the ignition magneto coil current is shorted to the ground. Since the current is shorted to the ground, no appreciable current can flow through the ignition coil primary winding due to the resistance of the winding. However, (assuming correct ignition timing) when the piston reaches a position 23° before top dead center, the contact breaker points open, interrupting the short to the ground and causing the current to flow instead through the primary winding. Then, as the points close, the current is once again shorted through the points and can no longer flow through the primary winding. This pulse in the primary winding produces a rapid build-up of a magnetic field.

Electrical Wiring

(467)



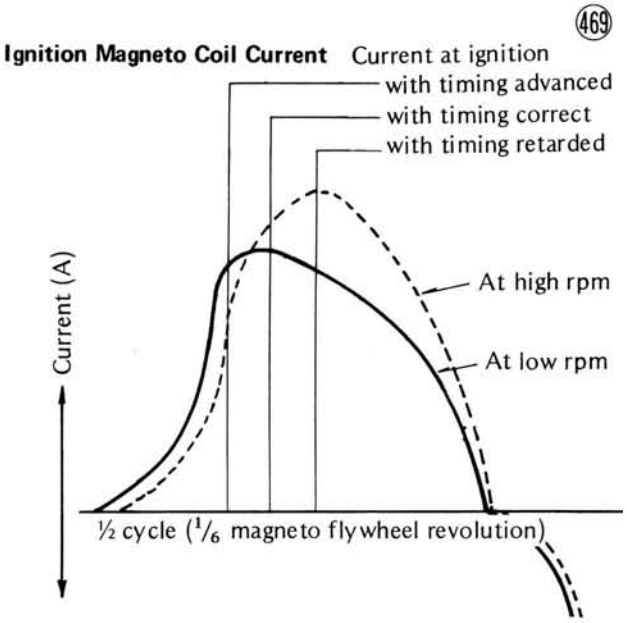
Ignition Circuit



The magnetic flux of this field cuts through the secondary winding, inducing current in the winding. The voltage of this current, dependent on the number of turns in the secondary winding and the speed of the rise of primary winding voltage, is much greater than the voltage in the primary winding. It is this high voltage that causes a spark to jump across the spark plug electrodes. Since a greater ratio of secondary winding turns over primary winding turns and a sharper rise of primary winding voltage increase the secondary winding voltage that is produced, a certain ratio of turns in the ignition coil has been chosen and a certain voltage rise sharpness (determined by condenser and breaker point performance) has been designed in the ignition system such that a spark of sufficient but not excessive strength will be produced.

The single phase alternating current that is generated in the ignition magneto coil fluctuates as the flywheel rotates and increases with the rpm. In order to accommodate this current, the ignition system is designed so that, at the flywheel position where ignition takes place, the generated current for both high and low rpm will be sufficient for good spark plug performance and yet not be excessive. Thus, when the ignition timing is not properly set, not only will there be a loss of power as with the battery ignition system, but also the strength of the current sent to the ignition coil will be inappropriate at certain rpm's. For example, at high rpm if the ignition timing is retarded, the contact breaker points open when the current is too high, resulting in burned points, overheating of the ignition coil, and accelerated spark plug electrode wear. On the other hand, at high rpm if the ignition timing is too far advanced, the contact breaker points open when the current is too low. This current, producing too weak a spark, causes the engine to misfire. Exceptionally retarded timing also results in too weak a spark, causing misfiring and difficult starting.

The contact breaker consists of one fixed and one movable contact point. The movable point is pivoted,



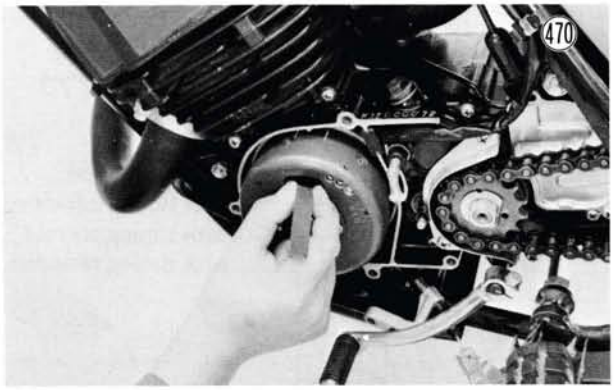
and the heel on one end is held against the cam surface on the flywheel hub by a single leaf spring. As the flywheel rotates, the heel rides on the cam surface, and, as the flywheel reaches the position where ignition takes place, the high spot on the cam surface pushes out on the heel, which opens the points. As the heel wears down, the point gap narrows, retarding ignition timing. Consequently, the ignition timing must be periodically adjusted to compensate for heel wear.

The condenser is connected in parallel across the contact breaker points and serves to prevent current from arcing across the points as they open. Arcing across the points would reduce the sharpness of the voltage rise in the primary winding, thus weakening the spark plug spark, and also damage the surface of the points. When the points are first opening, the condenser absorbs a certain amount of current, giving the points time to open far enough apart to where current will not arc across. However, if the condenser shorts, the current will simply be grounded through

the condenser whenever the points open. When the condenser is otherwise defective, the current will not be prevented from arcing across the points at the time of ignition, resulting in poor spark plug performance and burned and pitted points.

Contact Breaker

When the points become dirty, pitted, or burned, or if the spring weakens, the points will not make the contact necessary to produce a good spark, resulting in unstable idling, misfiring, or the engine not running at all. Inspect the contact breaker in accordance with the Periodic Maintenance Chart (Pg. 152), and repair or replace the points if necessary.



Clean the points with clean paper or cloth, or using an oil-free solvent. A business card soaked in trichloroethylene can be used to remove traces of oil. To repair light damage, use sandpaper or an oilstone. If the points are badly worn down or damaged, or if the spring is weak, replace the contact breaker.

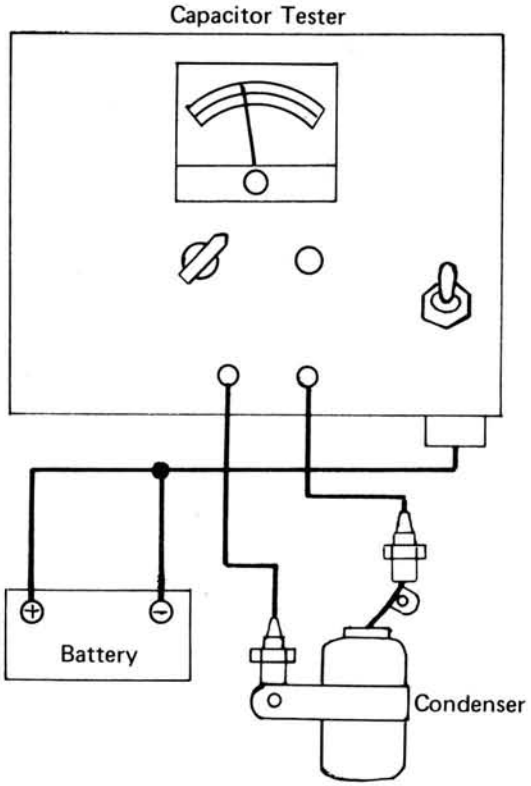
Whenever the contact breaker is inspected or replaced, apply a small amount of grease to the felt to lubricate the cam in order to minimize wear of the contact breaker heel. Be careful not to apply so much grease that it can drop off or be thrown onto the points, which will cause the points to foul and burn.

Condenser

The condenser can usually be considered to be defective if a long spark is seen arcing across the points as they open or if the points are burned or pitted for no apparent reason. Replace the condenser any time it appears defective and whenever the contact breaker is replaced.

NOTE: For checking with a capacitor tester, condenser specifications are: 0.25±0.03μfd., 1,000 WVDC.

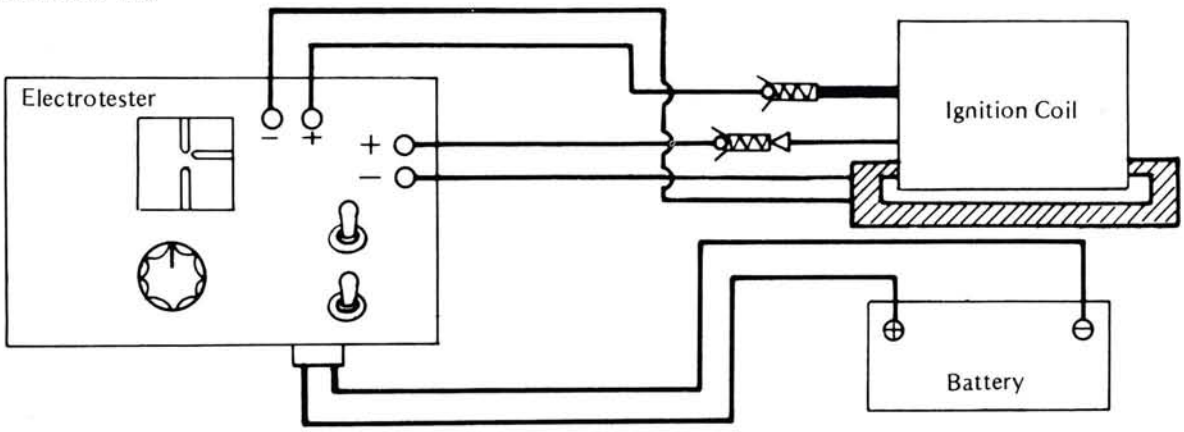
Condenser Test (471)



Ignition coil

The most accurate test for determining the condition of the ignition coil is made with the Kawasaki electrotester. The ignition coil must be connected to the tester in accordance to the tester directions and should

Ignition Coil Test (472)



produce at least a 5 mm (0.20 in) spark. Since an electrotester other than the Kawasaki electrotester may produce a different arcing distance, the Kawasaki electrotester is recommended for a reliable result.

If an electrotester is not available, the coil can be checked for a broken or a badly shorted winding with an ohmmeter. However, an ohmmeter cannot detect layer shorts and shorts resulting from insulation breakdown under high voltage.

To measure the primary winding resistance, set the ohmmeter to the R x 1 range, and connect one ohmmeter lead to ground and the other to the black lead from the ignition coil. The resistance should be 1.9 ~ 2.5Ω. To measure the secondary winding resistance, set the ohmmeter to the R x 100 range, and connect one ohmmeter lead to ground and the other to the spark plug lead. The resistance should be about 8 ~ 12KΩ.

If the coil does not produce an adequate spark, or if either the primary or secondary winding does not have the correct resistance, replace the ignition coil.

Ignition magneto coil

If the spark is weak or non-existent after the spark plug, ignition coil, points, and condenser are found to be all functioning properly, the wiring all in good condition and properly connected, and the ignition timing correctly adjusted, the cause may be a short or open in the ignition magneto coil or a loss of magnetism in the flywheel magnets.

- Rotate the magneto flywheel until the points open, and pull out the magneto harness plug from its socket near the fuel tap.
- Set an ohmmeter to the R x 1 range, and measure the resistance between ground and the magneto black lead. The proper value is between 1.1 ~ 1.6Ω.

If the resistance in this test is found to be less than the proper value, there is a short in the ignition magneto coil. Discontinuity indicates an open. In either case, replace the ignition magneto coil. If, however, the coil checks out good, the cause is probably a loss of magnetism in the flywheel, necessitating flywheel replacement.

LIGHTING/CHARGING SYSTEM

The lighting/charging coil and the lighting coil, which together with the ignition magneto coil make up the 3 coils mounted on the stator plate, are where the current is generated for the lighting/charging system. Each coil consists of a wire wrapped around a laminated steel core. One end of each wire is grounded at one side of its core, and the other end leaves the core as an output lead—pink for the lighting/charging coil and yellow for the lighting coil. The lighting/charging coil is tapped part way by a light blue lead. The lighting/charging coil pink lead supplies the current for the nighttime D C circuit, while its light blue lead supplies the current for the daytime D C circuit. The lighting coil lead supplies the current for the A C circuit.

To meet safety standards for lighting at low rpm, the lighting/charging system includes a battery in conjunction with the magneto to supply the current to the turn signals; horn; and brake, neutral, and tail lights. Since the battery, a D C device, must be charged by the magneto, an A C generator; a rectifier (Pg.140) must be included in the D C part of the lighting/charging system so that only direct current will flow in the lighting/charging coil and the D C lighting and charging circuits.

Daytime and nighttime D C	Nighttime lighting A C
1. turn signals	1. headlight
2. horn	2. speedometer light
3. brake light	3. tachometer light
4. neutral light	4. high beam indicator light
5. tail light (nighttime only)	

When the magneto flywheel rotates, magnetic flux cutting through these coils induces a current flow. As the engine speed increases, more magnetic flux cutting through the coils will increase the amount (amperage) and force (voltage) of this flow. But, to prevent an excessive current flow from burning out electrical components and overcharging the battery, the coil windings are designed to limit the amount of magnetic flux from the magneto magnets which may cut through the coils. The magnetic field that accompanies the current flow in the lighting/charging coil and lighting coil sector of the magneto will have sufficient opposition to the flywheel magneto magnetic field at high engine speed that the current flow that can be generated in the windings is limited to the maximum for which the circuit will accommodate.

However, a break (burned out bulb, missing battery, etc.), partial break (loose connection), short (rectifier or bare wire touching frame, a bridge across the resistance in a component, etc.), or partial short (bulb of too high a wattage) in any part of the lighting circuits will change the flux opposition. For example, if the headlight has burned out and the motorcycle is ridden with the ignition switch turned to the night position, not only will the other bulbs in the A C circuit be overloaded and burn out, but the increased resistance or break in the A C circuit will result in less or no current in the winding for the A C circuit. The drop in the flux opposition produced by the winding used for the A C circuit allows more flux in the flywheel magnetic field to cut through the winding used for the D C circuit. The resulting

excess D C voltage will blow the fuse or overcharge the battery and burn out D C circuit components. A short on the other hand may have the opposite effect, reducing the current for the components in both circuits.

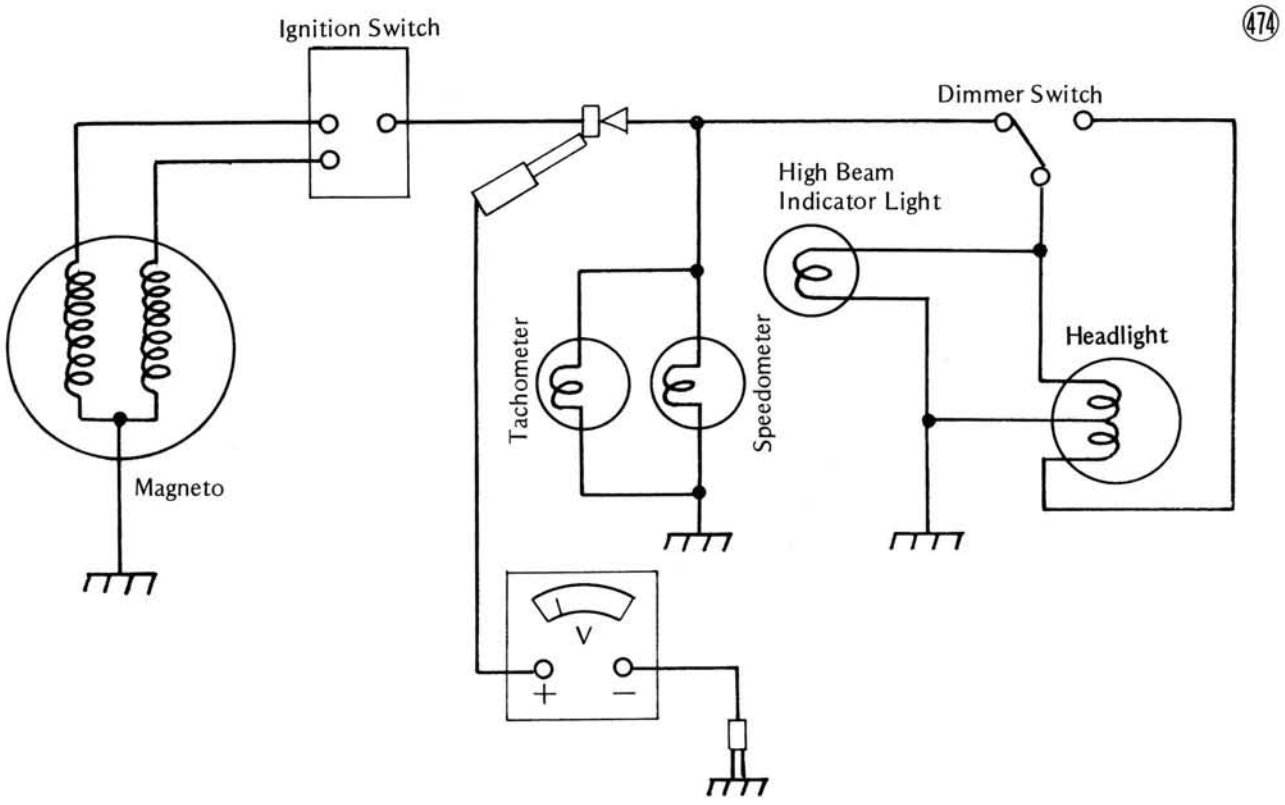
If the voltage produced for the lighting/charging system is insufficient, the lights will not fully light up, and the battery will discharge. If the battery, rectifier, and ignition switch are all functioning properly, the circuit loads (horn and all lights) not defective and of the correct wattage, and the wiring all properly insulated with no loose or tarnished connections, then insufficient voltage means a defective coil or a defective flywheel. A short or break in one of the coil wires may result in either a low output or no output at all. A loss of flywheel magnetism, which may be caused by aging or the flywheel being dropped or struck, will result in a low output.

Lighting/charging coil and lighting coil

The condition of the coils is determined by measuring the voltage of the A C output and the voltage and amperage of the daytime and nighttime D C outputs. Before making this test, check the condition of the battery (Pg. 140) and the rectifier (Pg. 140). The battery must be charged if the voltage is less than 6 volts, and the rectifier replaced if defective. Also, check to see that all circuit loads (headlight, tail light, horn etc.) are of the correct wattage.

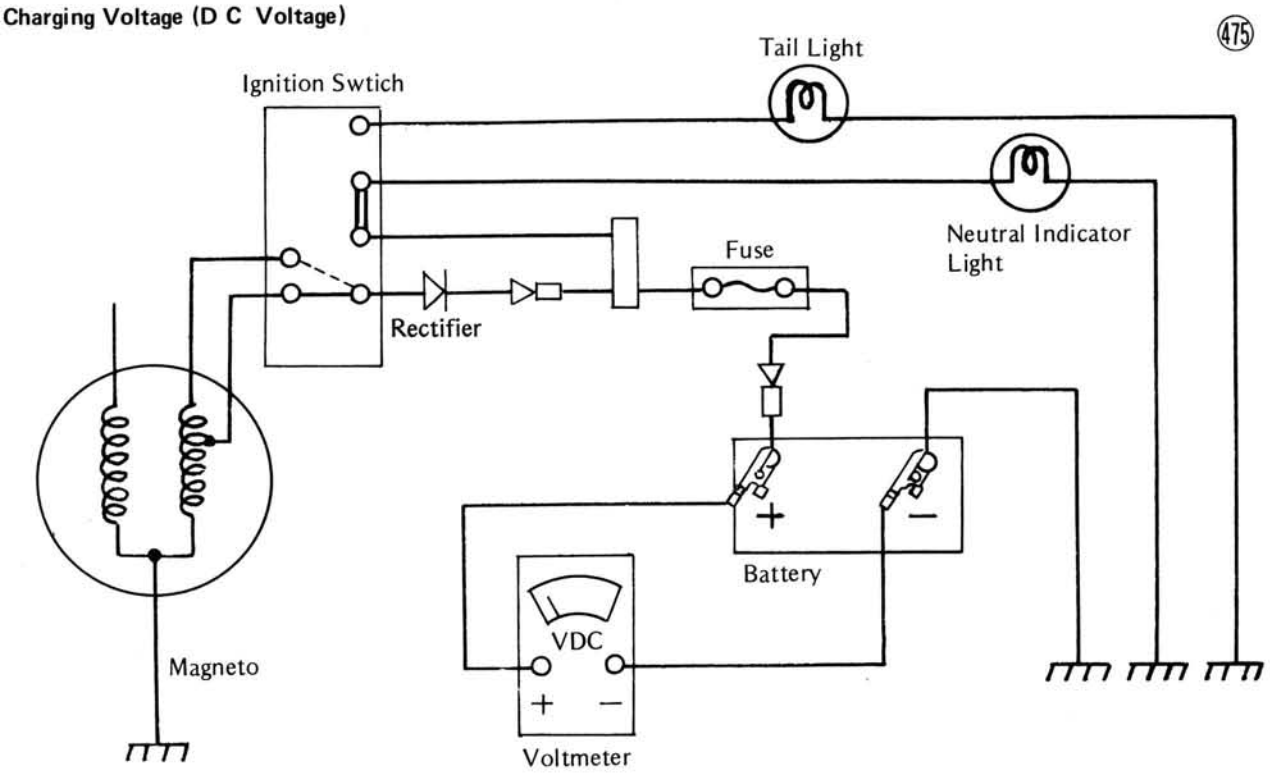
- Remove the engine sprocket cover and the left engine cover leaving the clutch cable still attached.
- Start the engine, and set the engine speed at 4,000 rpm.
- To measure the A C voltage produced by the magneto, first switch on the headlight, tail light, high beam indicator light, tachometer light, and speedometer light by turning the ignition switch to the night position and the dimmer switch to high beam.
- See that these lights are all lit.
- Connect a multimeter, set to 12 or 30 VAC, in parallel across the A C circuit load by connecting the + meter lead to the red lead on the ignition switch and the – meter lead to ground. The voltage should be 6~7.4 VAC.
- Disconnect the meter leads.
- To measure the nighttime D C voltage produced by the magneto, connect the multimeter, set to 12 or 30 VAC, across the battery by connecting the – meter lead to the battery – terminal and the + lead to the battery + terminal. The voltage should be 8.5~8.6 VDC.
- Turn the ignition switch to the daytime position to measure the daytime D C voltage. The voltage should be 8.5~8.6 VDC.
- Disconnect the meter leads, and turn off the engine.
- Set the multimeter to the 12 Amp DC range.
- Disconnect the lead between the fuse and the rectifier where the white lead connects to the white lead. Connect the – meter lead to the white lead on the fuse side, and connect the + meter lead to the white lead on the rectifier side. This puts the meter in series with the rectifier and battery so that the battery charging amperage can be measured.
- Turn the ignition switch to the daytime position, and start the engine.
- Set the engine to 4,000 rpm. The reading should be 0.7 amps or more.

Lighting Voltage (A C Voltage)

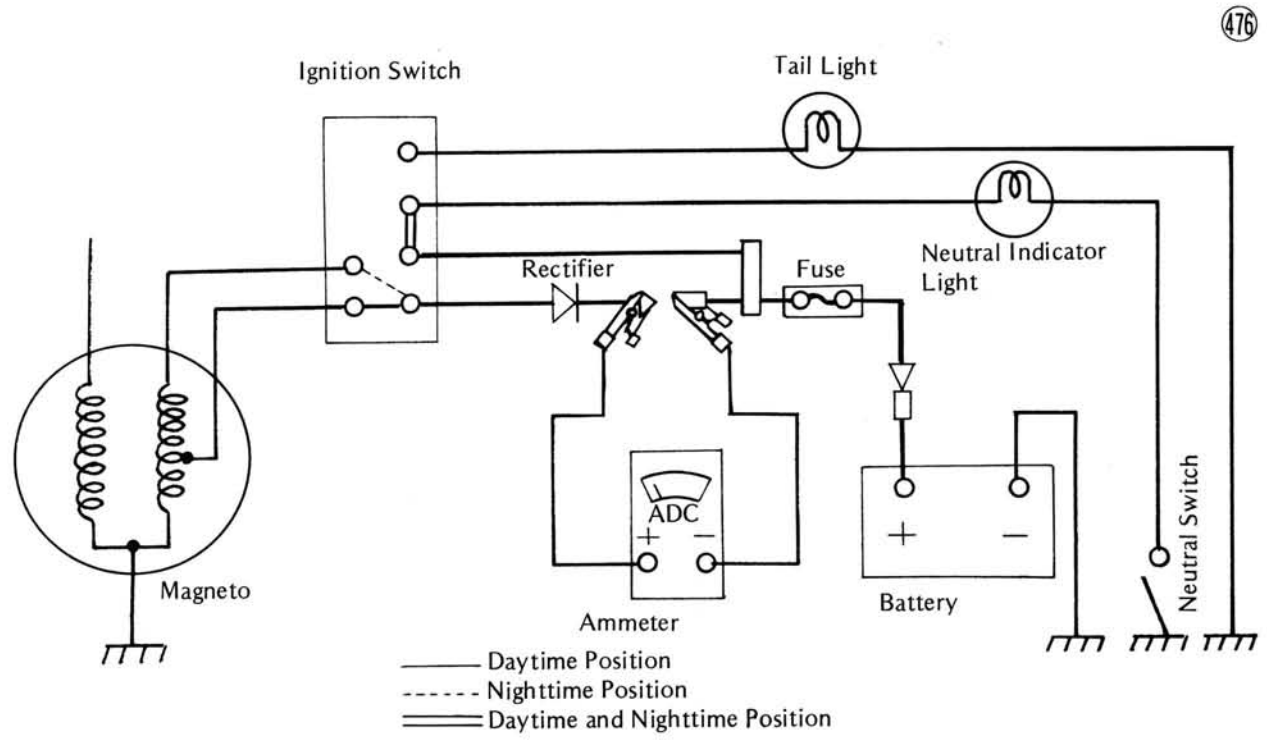


●To measure the nighttime charging amperage, first turn the ignition switch to the nighttime position. Check to see that the headlight, high beam indicator light, speedometer light, tachometer light, and tail light are all lit. The reading should be 1 amp or more. Turn off the engine.

Charging Voltage (D C Voltage)



Charging Amperage (D C Amperage)



If any one of the above checks shows a low reading, the lighting/charging system is not functioning satisfactorily. Since the components outside the magneto itself have been determined to be in proper order, the trouble must be either with the coils or with the magneto flywheel.

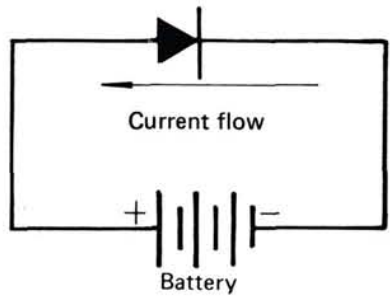
- Disconnect the magneto output connector under the fuel tank.
- Setting the multimeter to R x 1, measure the resistance between ground and each magneto output lead. The resistance between ground and light blue should be 4.3~6.6Ω; between ground and pink, 2.0~3.1Ω; and between ground and yellow, 0.36~0.54Ω. Less than the proper resistance means a coil short; higher than the proper resistance or no reading at all means a break in the coils. In case of a short or break, replace the lighting/charging coils as a set.

If the coils have normal resistance, but the voltage and amperage checks show the lighting/charging system to be defective, then the permanent magnets in the flywheel have probably weakened, necessitating flywheel replacement.

RECTIFIER

The rectifier, consisting of a diode mounted on a plate for heat dissipation, ensures that only direct current goes for charging the battery, lighting the tail light, and operating the components of the daytime D C circuit. The reason that the rectifier only permits direct current to flow in the circuit in which it is included is that a diode conducts appreciable current in only one direction. However, a defective diode will conduct in both directions (a short) or not conduct at all (a break).

Diode

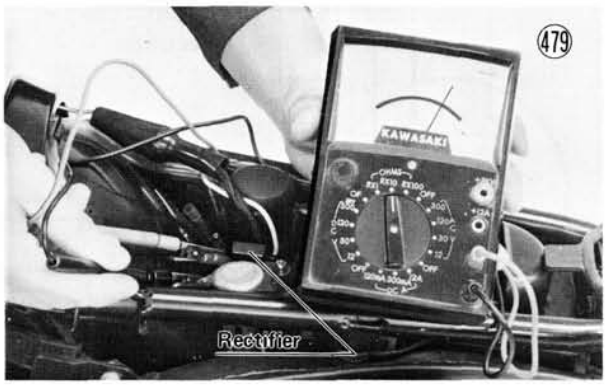


If the rectifier becomes defective, the battery will discharge. A defective rectifier can be readily detected with a resistance check.

NOTE: If the motorcycle is operated with the battery left unconnected, the rectifier will become damaged due to an excessive reverse bias voltage.

Rectifier check

With the engine off, disconnect the blue/white rectifier lead from the blue/yellow lead, and disconnect the brown/white rectifier lead from the brown/white lead. Setting an ohmmeter to the R x 10 or R x 100 range, check the resistance between the blue/white and the brown/white rectifier leads. The resistance should be low in one direction and more than ten times as much in the other direction.



NOTE: The actual meter reading varies with the meter used and with the individual rectifier, but, generally speaking, the lower reading should be within 1/3 scale of zero ohms.

If the meter reads low or high in both directions, the rectifier is defective and must be replaced.

BATTERY

The battery is a back-up source of power to operate the tail light, brake light, turn signals, and horn whenever the engine is turning too slowly for the magneto to supply sufficient power. However, the battery does not back-up either the ignition or the headlight, both of which are in circuits not connected to the battery.

With proper care, the battery can be expected to last a few years, but it may be completely ruined long before that if it is mistreated. Following a few simple rules will greatly extend the life of the battery.

1. **When the level of the electrolyte in the battery is low, add only distilled water to each cell until the level is at the upper level line marked on the outside of the battery. Ordinary tap water is not a substitute for distilled water and will shorten the life of the battery. Distilled water comes in a sealed, non-metallic container; any other water is not distilled water.**
2. **Never add sulphuric acid solution to the battery. This will make the electrolyte solution too strong and will ruin the battery within a very short time.**

3. **Avoid quick-charging the battery. A quick-charge will damage the battery plates.**
4. **Never let a good battery stand for more than 30 days without giving it a supplemental charge, and never let a discharged battery stand without charging it. If a battery stands for any length of time, it slowly self-discharges. Once it is discharged, the plates sulphate (turn white), and the battery will no longer take a charge.**
5. **Keep the battery well charged during cold weather so that the electrolyte does not freeze and crack open the battery. The more discharged the battery becomes, the more easily it freezes.**
6. **Always keep the battery vent hose free of obstruction, and make sure it does not get pinched or crimped shut. If battery gases cannot escape from this hose, they will explode the battery.**
7. **DON'T INSTALL THE BATTERY BACKWARDS. The negative side is grounded.**

Electrolyte

The electrolyte is dilute sulphuric acid. The standard specific gravity of the electrolyte used in warm climates in a fully charged battery is 1.260 at 20°C (68°F). In particularly cold regions a solution with a standard specific gravity of 1.280 is used. The water in this solution changes to a gaseous mixture due to chemical action in the battery and escapes, which concentrates the acid in a charged battery. Consequently, when the level of the electrolyte becomes low, only distilled water should be added. If sulphuric acid is added, the solution will become too strong for proper chemical action and will damage the plates. Metal from the damaged plates collects in the bottom of the battery. This sediment will eventually cause an internal short circuit.

The specific gravity of the electrolyte is measured with a hydrometer and is the most accurate indication of the condition of the battery. When using the hydrometer, read the electrolyte level at the bottom of the meniscus (curved surface of the fluid). Fig. 480 shows the relationship between the specific gravity of the solution at 20°C (68°F) and the percentage of battery charge. Since specific gravity varies with temperature, and since the temperature of the solution being checked is likely to be other than 20°C (68°F), the formula given below should be used to compute what the specific gravity would be if the temperature were 20°C (68°F). When the temperature goes up, the specific gravity goes down, and vice versa.

Celsius

$$S_{20} = S_t + [0.0007\ (t - 20)]$$

Fahrenheit

$$S_{68} = S_t + [0.0004\ (t - 68)]$$

S_t = specific gravity at the present temperature

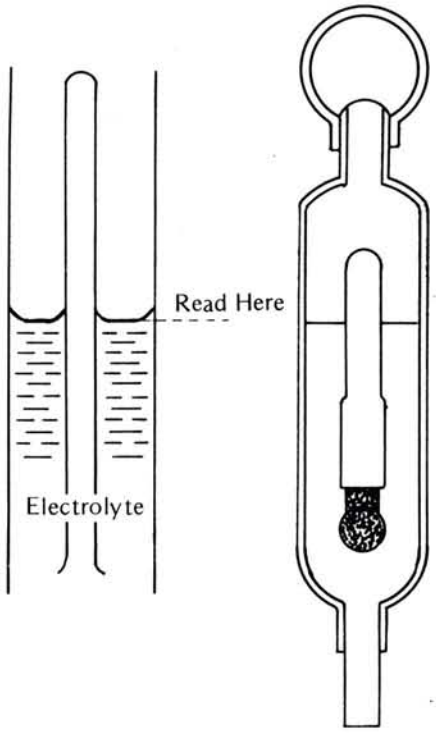
S_{20} = specific gravity at 20°C

S_{68} = specific gravity at 68°F

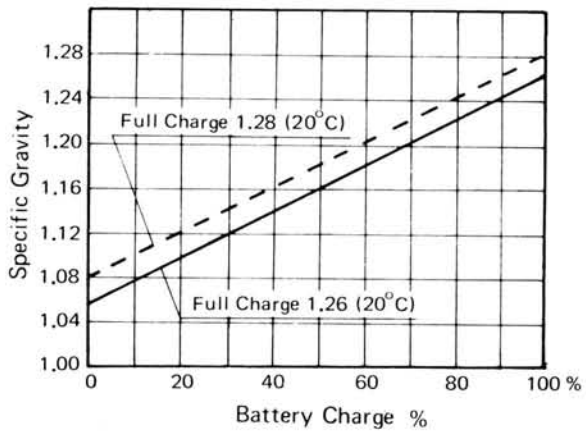
t = present temperature of solution

Generally speaking, a battery should be charged if a specific gravity reading shows it to be discharged to 50 % or less of full charge.

Hydrometer (480)



Specific Gravity/Battery Charge Relationship (481)



Initial charge

New batteries for Kawasaki motorcycles are dry charged and can be used directly after adding the electrolyte. However, the effect of the dry charge deteriorates somewhat during storage, especially if any air has entered the battery from imperfect sealing. Therefore, it is best to give the battery an initial charge before using it in order to ensure long battery life.

CAUTION: Because the battery gives off an explosive gas mixture of hydrogen and oxygen, keep any sparks or open flame away from the battery during charging.

- Pour a 1.260 (specific gravity at 20°C or 68°F) sulphuric acid solution into each cell of the battery up to the upper line.
- Let the battery stand for 30 minutes, adding more acid if the level drops during this time.

NOTES: 1. If the temperature of the solution is over 30°C (85°F), cool the solution before pouring it into the battery.
2. After pouring the acid into the battery, start charging the battery within 12 hours.

- Leaving the caps off the cells, connect the battery to a charger, set the charging rate at 1/10 the battery capacity, and charge it for 10 hours. For example, if the battery is rated at 6AH, the charging rate would be 0.6 ampere. If a constant voltage charger is used, the voltage must be adjusted periodically to keep the current at a constant value.

CAUTION: If the temperature of the electrolyte rises above 45°C (115°F) during charging, reduce the charging rate to bring down the temperature, and increase the charging time proportionately.

- After charging, check the electrolyte level in each cell. If the level has dropped, add distilled water to bring it back up to the upper line.
- Check the results of charging by measuring the specific gravity of each cell and by measuring battery voltage. Battery voltage of a 6 volt battery directly after the completion of charging should be 7.5 to 8.0 volts.

Ordinary charge

CAUTION: Because the battery gives off an explosive gas mixture of hydrogen and oxygen, keep any sparks or open flame away from the battery during charging.

- Clean off the battery using a solution of baking soda and water. Make especially sure that the terminals are clean.
- If the electrolyte level is low in any cell, fill to over the lower line but not up to the upper line since the level rises during charging. Figure the charging rate to be between 1/10 and 3/10 of battery capacity. For example, the maximum charging rate for a 6AH battery would be 3/10 x 6 which equals 1.8 amperes.

CAUTION: Charging the battery at a rate higher than specified above could ruin the battery. Charging at a higher rate causes excess heat, which can warp the plates and cause internal shorting. Higher than normal charging rates also cause the plates to shed active material. Deposits will accumulate, and can cause internal shorting.

- Measure the specific gravity of the electrolyte, and use the graph, Fig. 481 , to determine the percentage of discharge. Multiply the capacity of the battery by the percentage of discharge to find the amount of discharge in ampere-hours. Use this figure in the formula below to compute charging time.

$$\text{charging time (hours)} = \frac{\text{amount of discharge (AH)}}{\text{charging current (A)}} \times 1.2 \sim 1.5$$

- Remove the caps from all the cells, and begin charging the battery at the rate just calculated. If a constant voltage charger is used, the voltage will have to be adjusted periodically to maintain charging current at a constant value.

CAUTION: If the temperature of the electrolyte rises above 45° C (115°F) during charging, reduce the charging rate to bring down the temperature, and increase charging time proportionately.

- After charging, check the electrolyte level in each cell. If the level has dropped, add distilled water to bring it back up to the upper line.
- Check charging results by measuring the specific gravity of each cell and by measuring battery voltage. Battery voltage of a 6 volt battery directly after the completion of charging should be 7.5 to 8.0 volts. If the voltage is lower than this, the battery is not completely charged or can no longer take a full charge.

Test charging

When the battery is suspected of being defective, first inspect the points noted in the chart below. The battery can be tested by charging it by the ordinary charge. If it will take a charge so that the voltage and specific gravity come up to normal, it may be considered good except in the following cases:

★ If the voltage suddenly jumps to over 7.0 volts just after the start of charging, the plates are probably sulphated. A good battery will rise to 6 volts immediately and then gradually go up to 6.3 ~ 6.5 volts in about 30 to 60 minutes after charging is started.

★ If one cell produces no gas or has a very low specific gravity, it is probably shorted.

Table 60 Battery Troubleshooting Guide

	Good Battery	Suspect Battery	Action
Plates	(+) chocolate color (–) gray	white (sulphated); + plates broken or corroded	Replace
Sediment	none, or small amount	sediment up to plates, causing short	Replace
Voltage	above 6 volts	below 6 volts	Test charge
Electrolyte Level	above plates	below top of plates	Fill and test charge
Specific Gravity	above 1.200 in all cells; no two cells more than 0.020 different	below 1.100, or difference of more than 0.020 between two cells	Test charge

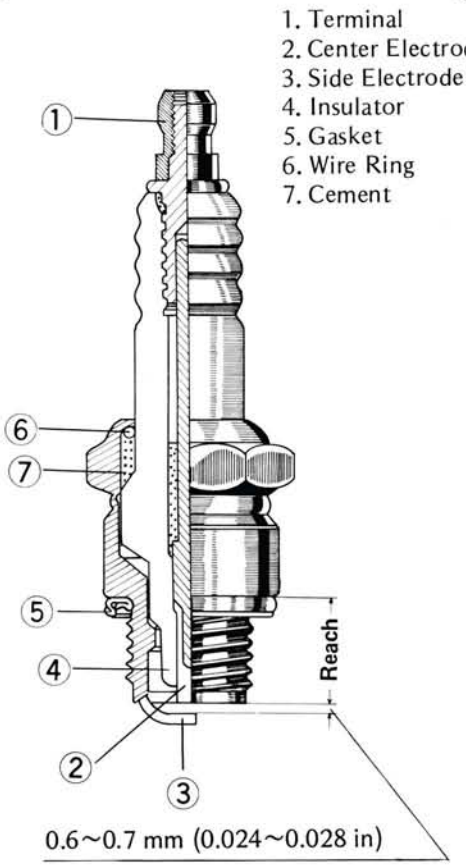
★ If there does not appear to be enough sediment to short the plates, but one cell has a low specific gravity after the battery is fully charged, the trouble may be just that there is insufficient acid in that cell. In this case only, sulphuric acid solution may be added to correct the specific gravity.

★ If a fully charged battery not in use loses its charge after 2 to 7 days, or if the specific gravity drops markedly, the battery is defective. The self-discharge rate of a good battery is only about 1% per day.

SPARK PLUG

The spark plug ignites the fuel/air mixture in the combustion chamber. To do this effectively and at the proper time, the correct spark plug must be used, and the spark plug must be kept clean and adjusted.

Spark Plug (482)



Tests have shown the NGK B8HS, set to a 0.6 ~ 0.7 mm (0.024 ~ 0.028 in) gap to be the best plug for general use. But since spark plug requirements change with ignition and carburetion adjustments and with riding conditions, this plug may have to be replaced with one of the next higher or lower heat range. Whether or not a spark plug of a different heat range should be used is generally determined upon removing and inspecting the plug.

When a plug of the correct heat range is being used, the electrodes will stay hot enough to keep all the carbon burned off but cool enough to keep from damaging the engine and the plug itself. This temperature is about 400 ~ 800°C (750 ~ 1450°F) and can be judged by noting the condition and color of the ceramic insulator around the center electrode. If the ceramic is clean and of a light brown color, the plug is burning at the right temperature.

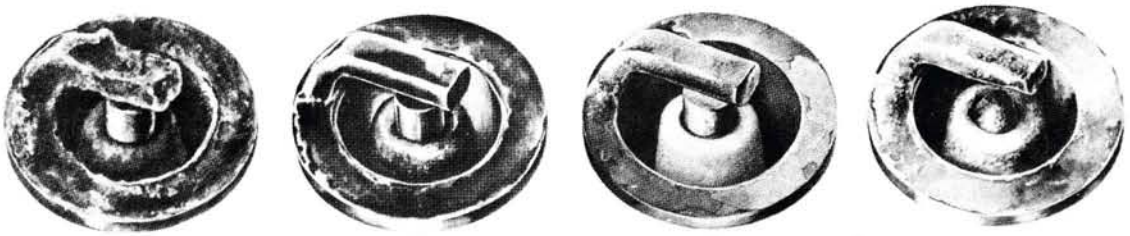
A spark plug for higher operating temperatures is used for racing and other high speed applications. Such a plug is designed for better cooling efficiency so that it will not overheat and thus is often called a "colder" plug. If a spark plug with too high a heat range is used—that is, a "cold" plug that cools itself too well—the plug will stay too cool to burn off the carbon, and the carbon will collect on the electrodes and the ceramic insulator. If enough of this carbon collects, it may prevent a spark from jumping across the gap, or it may short the spark out by bridging across the electrodes or by conducting along the outside of the ceramic. Carbon build-up on the plug can also cause the electrodes to heat up red-hot, which will cause preignition, indicated by knocking, which in turn may eventually burn a hole in the top of the piston.

A spark plug in the lower heat range is used when engine temperature is comparatively low such as for constant city use or during the break-in period when the motorcycle is not operated at high speed. Such a plug is designed to hold the heat and thus is often referred to as a "hotter" plug. If a "hot" plug is used for racing or other high speed use, the plug will be too hot, causing engine overheating and preignition.

Inspection and replacement

Remove the plug and inspect the ceramic insulator. If the insulator is clean and has a light brown color, the correct plug is being used. If it is fouled black,

Spark Plug Condition (483)



Carbon Fouling | Oil Fouling | Normal Operation | Overheating

change to the "hotter" NGK B7HS. If the ceramic is burned white and the electrodes are burned, replace the plug with the "colder" NGK B9HS. However, if the spark plug still fouls or overheats after changing to a hotter or colder plug, the cause of the trouble may be other than the spark plug such as faulty carburetion or ignition timing.

CAUTION: When the type of riding changes—for example, a change to faster riding after the break-in period is over—the spark plug should be inspected and changed if necessary. The NGK B7HS plug in particular can damage the engine if used for high speed riding.

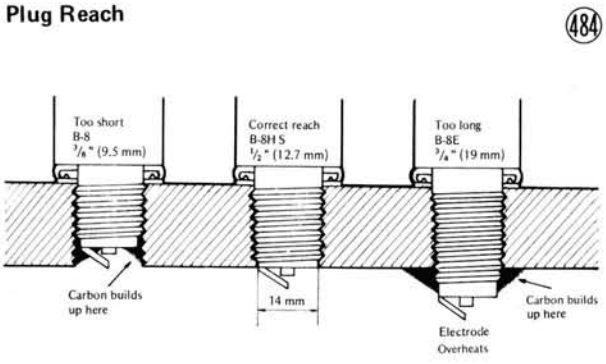
Clean the electrodes and the ceramic insulator around the center electrode by scraping off any deposits and cleaning the plug in a high flash-point solvent. If the gap has widened, reset it to the standard 0.6 ~ 0.7 mm (0.024 ~ 0.028 in) gap. If the electrodes are badly worn down or burned, replace the plug. The plug must also be replaced any time there is visible damage such as cracked ceramic or damaged threads.

NOTE: If the spark plug is replaced by any other than th recommended NGK B7HS, B8HS (standard), or B9HS, make sure that the replacement plug has the same:

(1) thread pitch
(2) reach (length of thread portion must be 12.7 mm (1/2 in.))
(3) diameter (diameter at threads must be 14 mm (9/16 in.))

If a plug with the wrong thread pitch or thread diameter is used, the cylinder head will be damaged. If a plug with too long or short a reach is used, carbon will build up around the plug or plug hole threads, possibly causing engine damage and making the old plug difficult to remove or the new one difficult to install.

Plug Reach



IGNITION SWITCH

The ignition switch has three positions: off, daytime, and nighttime. In the off position the ignition lead is grounded, preventing the engine from running since current from the ignition magneto coil shorts to the ground instead of going to the ignition coil. The circuits for the lighting/charging system are open, and the key can be removed from the switch. In the daytime position the ignition lead is disconnected from ground so that the engine can be started. A lead from the magneto is connected to the rectifier to charge the battery, and a lead from the battery is connected to the horn, turn signals, brake light, and neutral indicator light circuits. In the nighttime position a different lead from the magneto is connected to the rectifier to charge the battery, the lead from the battery is also connected to the tail light circuit, and a lead from the magneto is connected to the headlight circuit. When the key is in either the daytime or nighttime position, it cannot be removed from the ignition switch.

Testing the switch

Table 61 shows the internal connections of the ignition switch for each switch position. To check the switch, disconnect the lead plug from the switch, and use an ohmmeter to verify that there is continuity (zero ohms) between all the connections that are listed in the table for each switch position, and that there is no continuity between the leads that are not connected. If the switch has an open or short, it can be disassembled for repair. The contact surfaces may be cleaned, but no internal parts are available for replacement. If any parts are not repairable, the switch must be replaced as a unit.

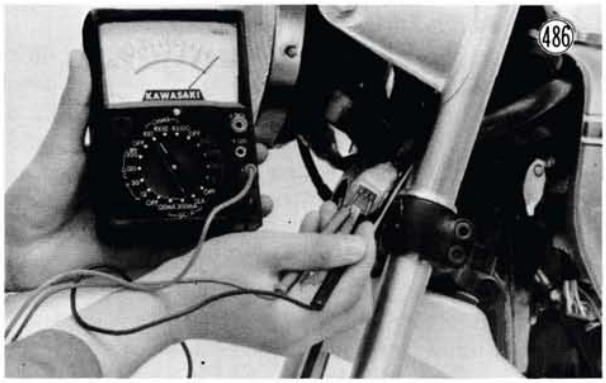
HEADLIGHT CIRCUIT

The headlight circuit is shown in Fig. 487 . When the engine is running and the ignition switch is turned to the nighttime position, the headlight circuit is completed, turning on the headlight, speedometer light, and tachometer light. The dimmer switch is used to select high or low beam. When the headlight is on high beam, the high beam indicator light also is lit.



Headlight trouble

If the headlight does not light, check to see if the bulb has burned out. If the bulb has burned out, the sealed beam unit must be replaced. If the bulb is good, **check the dimmer switch. Table 62 shows the connections in the dimmer switch for both high and low** beam. Disconnect the leads to the dimmer switch, and use an ohmmeter to see that only the connections shown in the table have continuity (zero ohms). If the switch has an open or a short, it can be disassembled for repair. The contact surfaces may be cleaned, but no internal parts are available for replacement. If any parts are not repairable, the switch must be replaced as a unit. However, if the dimmer switch is good, check the ignition switch, the wiring, and the magneto.

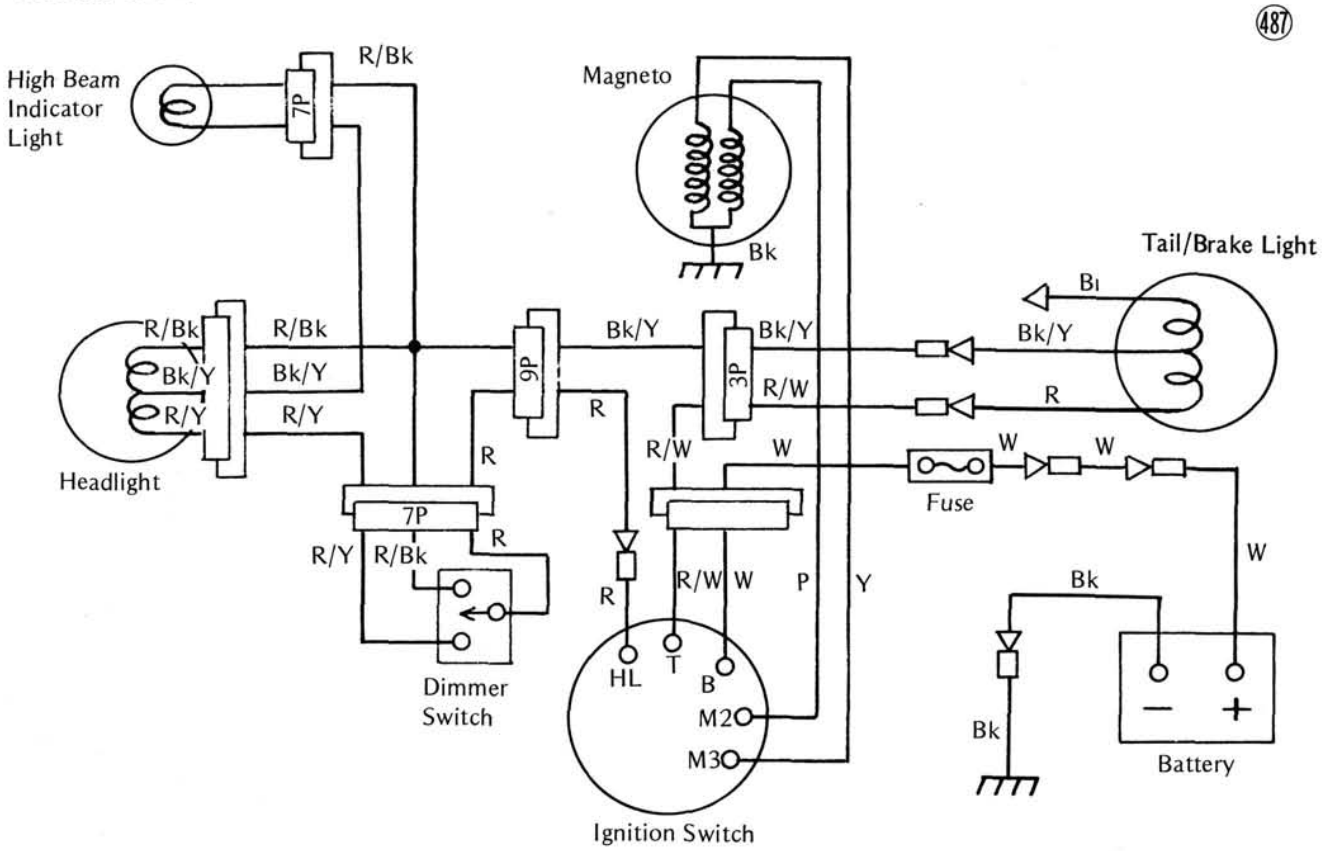
High Beam		●	●
Low Beam	●	●	

If the headlight lights but does not light brightly, the trouble may be that the headlight is of the improper wattage or that the magneto is not putting out sufficient current. However, the trouble may be also caused by a short or a component drawing too much current in some other part of the lighting/charging system.

Headlight Circuit



BRAKE AND TAIL LIGHT CIRCUIT

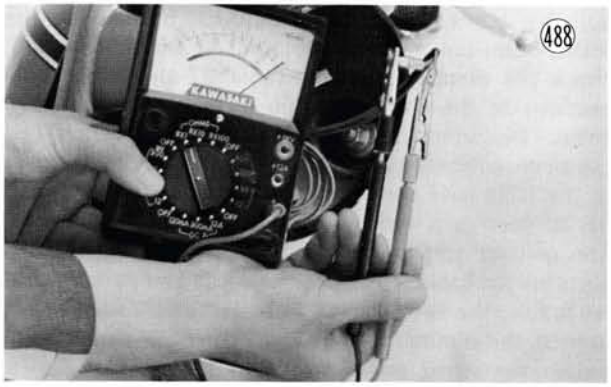
The brake and tail light circuit is shown in Fig. 489. The same bulb is used for both the brake and tail lights, but the bulb has a separate filament for each light. Each filament is controlled by a separate part of the brake and tail light circuit. When the ignition switch is turned to either the daytime or nighttime position, the brake light goes on whenever the circuit is closed by either the front or rear brake light switch. The tail light is lit whenever the ignition switch is turned to the nighttime position.

The front brake light switch, mounted on the front brake lever body, is actuated when pressed by the front brake lever. The rear brake light switch is actuated when pulled on by the rear brake pedal. Both switches are a sealed plunger type of switch, which cannot be disassembled and must be replaced as a unit if defective. The front brake light switch does not require any adjustment, but the rear switch must be adjusted by changing its position higher or lower in the mounting bracket so that the brake light goes on after a certain amount of brake pedal travel when the brake pedal is applied (Pg. 18).

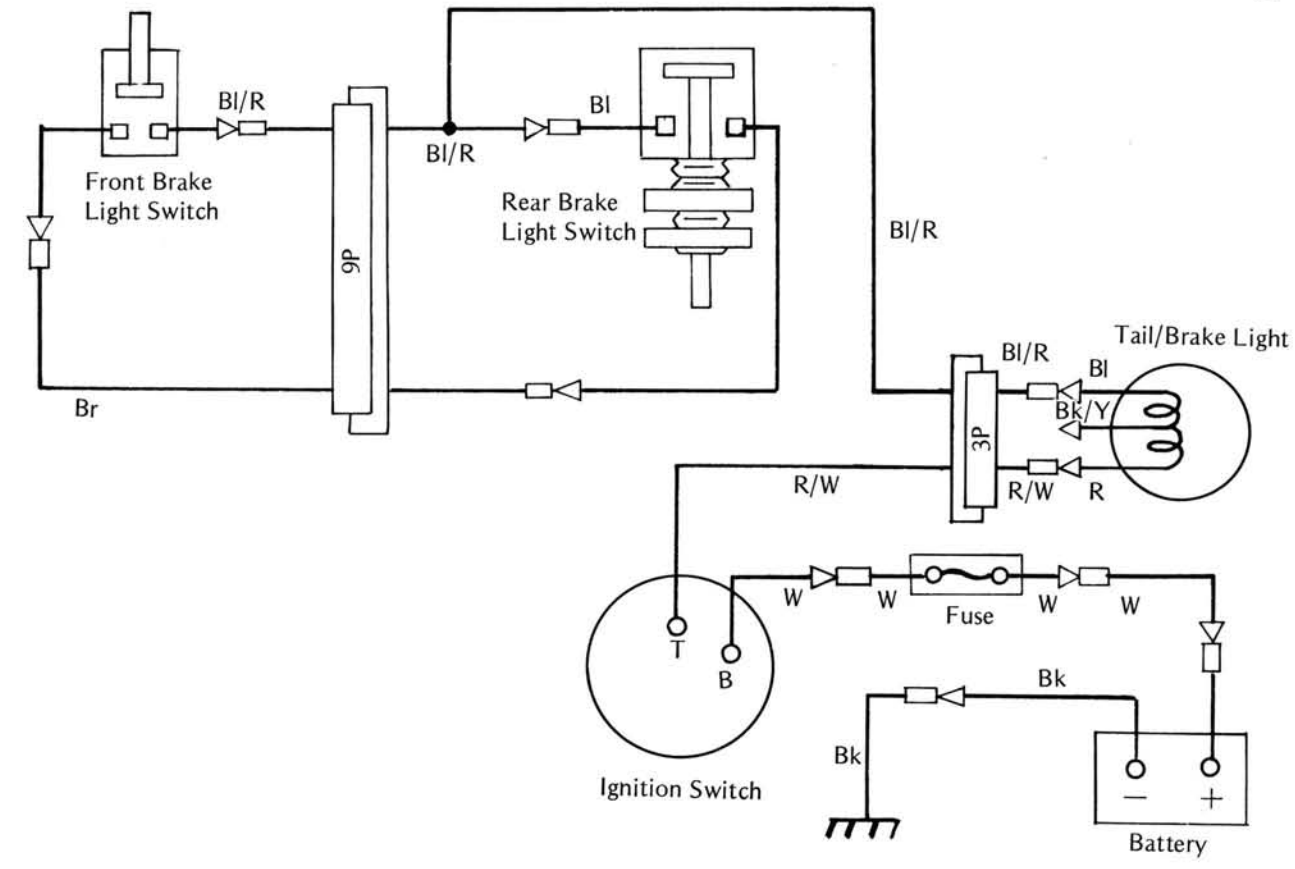
Brake light trouble

If the ignition switch is in the daytime or nighttime position and the brake light does not go on when either the front or rear brake is applied, first push the horn button and flip the turn signal switch to see if the fuse, ignition switch, or battery may be defective. If the turn signals and horn work, check for a burned out brake light filament. If the bulb is good, the trouble is either the wiring or the brake light switches.

To check the front brake light switch, first disconnect from inside the headlight housing the brown and the blue/red switch leads. Connect an ohmmeter to the switch leads, and pull the front brake lever. The ohmmeter should read zero ohms. If it does not, replace the switch. If the switch checks out okay but the brake light does not light, check the wiring.



Brake Light Circuit



To check the rear brake light switch, disconnect from in front of the air cleaner housing the brown and the blue/red switch leads. Connect an ohmmeter to the switch leads, and pull the switch plunger. The ohmmeter should read zero ohms. If it does not, replace the switch.

Tail light trouble

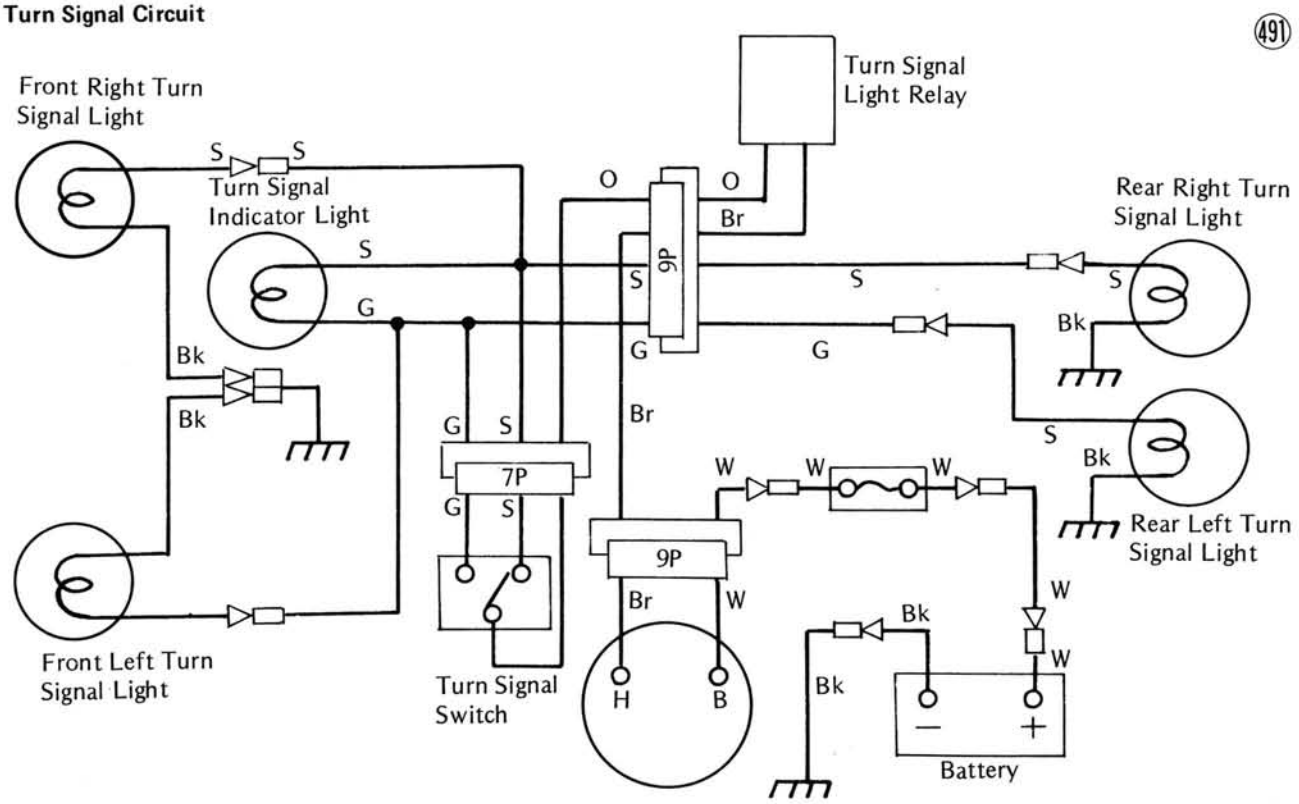
If the tail light does not go on when the ignition switch is turned to the nighttime position, the filament is probably burned out. However, if the bulb is good, check the wiring, ignition switch, fuse, and battery.

TURN SIGNALS

A wiring diagram of the turn signal circuit is shown in Fig. 491 . When the ignition switch is in the daytime or nighttime position and the turn signal switch is turned to R or L, a ground is provided for the circuit so current can flow. Current to the right or left turn signals flows through the closed contacts and the resistance wire inside the turn signal relay, and the turn signals go on. The resistance wire quickly heats up, expands, and allows a spring to pull the contacts open. When the contacts have opened, the circuit is broken, the turn signals go off, and the resistance wire cools and contracts, closing the contacts so that the cycle can begin again. The indicator light in the turn signal circuit flashes on and off with the turn signals to indicate that they are working properly.

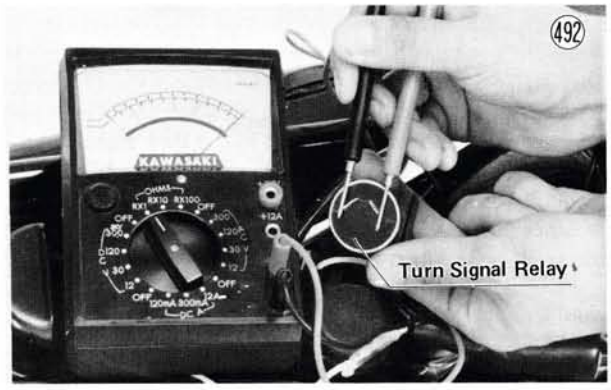
Since the turn signal relay is designed to operate correctly only when two turn signals (one front and one rear) and the turn signal indicator light are properly connected in the circuit, trouble may result from a burned out bulb, a bulb of incorrect wattage, loose wiring, as well as from a defect in the relay itself. In general, if the trouble with the circuit is common to both right and left turn signals, it is probably caused by a defective turn signal relay, although it may be due to a bad switch, wiring, or battery. If the trouble is with only one side—either right or left—then the relay is not at fault since the same relay is used for both sides.

Turn Signal Circuit

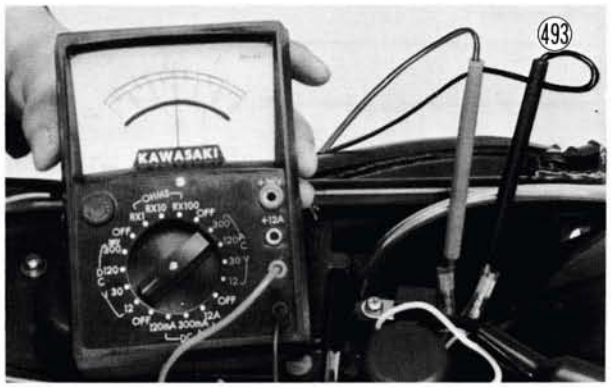


Turn signal trouble

(1)Neither right nor left turn signals come on at all:
- Check that battery voltage is normal.
- Unplug the relay leads and use an ohmmeter to check that there is continuity (close to zero ohms) between the relay terminals. If there is no ohmmeter reading, or if there is several ohms resistance, replace the relay with a new one.



- If the relay checks good, turn the meter to the 12 VDC range, connect the + meter lead to the brown lead that was disconnected from the relay, and connect the – meter lead to the orange lead. With the ignition switch on, first switch the turn signal switch to the R and then to the L position. The meter should register battery voltage at either position. If it does not, the fuse, ignition switch, or wiring is at fault. If battery voltage is read on the meter but the turn signals will still not work when the relay is reconnected, then recheck all wiring connections.



(2)Both right or both left turn signals come on and stay on or flash too slowly:
- Check that battery voltage is not low.
- Check that all wiring connections are good.
- Check that the turn signal bulbs and indicator bulb are of the correct wattage.
- If all of the above check good, replace the relay.

(3)A single light on one side comes on and stays on:
- Either the light that does not come on is burned out or the wiring is broken or improperly connected.

(4)Neither light on one side comes on:
- Unless both lights for that side are burned out, the trouble is with the turn signal switch.

(5)Flashing rate is too fast:
- If this occurs on both the right and left sides, check that the battery is not being overcharged. If the flywheel magneto and battery voltage are normal, replace the turn signal relay.
- If this occurs on only one side, one or both of the turn signal bulbs are of too high a wattage.

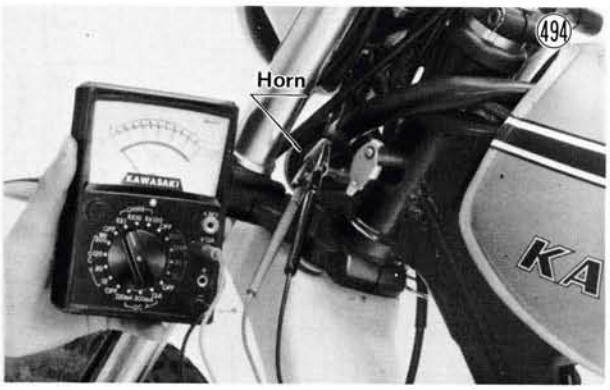
HORN CIRCUIT

The horn circuit and construction are shown in Fig. 495 . When the horn button is pressed with the ignition switch in either the daytime or nighttime position, the horn is grounded to complete the horn circuit. Current then flows through the horn contacts and horn coil, magnetizing the iron core. The magnetized iron core pulls on the armature and diaphragm assembly, the movement of which pushes open the contacts, interrupting the current flow. Since the core now loses its magnetism, the armature and diaphragm assembly springs back to its original position, closing the contacts. This cycle repeats until the horn button is released. Since each cycle takes only a fraction of a second, the diaphragm moves fast enough to produce sound.

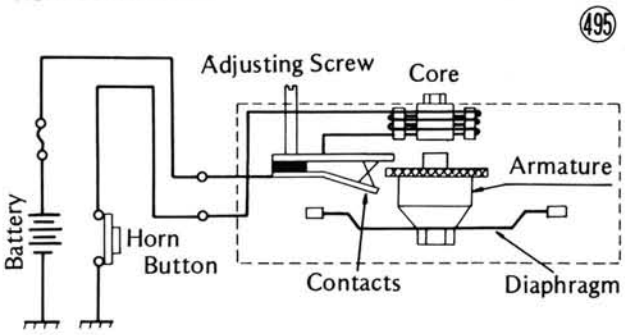
The contacts wear down after long use, requiring adjustment from time to time (Pg. 21). If the horn itself is determined to be at fault and adjustment fails to correct the trouble, the contacts or some other component in the horn is defective. The horn cannot be disassembled and must be replaced if defective.

Horn trouble

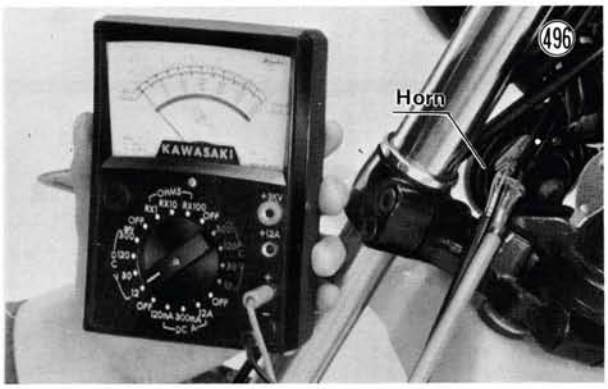
- Check that battery voltage is normal.
- Disconnect the leads to the horn, and connect to the horn terminals a multimeter set to the R x 1 range to check for continuity (close to zero ohms). If the reading is several ohms or if there is no reading at all, replace the horn.



Horn Construction



- If the reading is very close to zero, set the multimeter to the 12 VDC range, and connect the meter to the leads that were disconnected from the horn. The + meter lead goes to the brown lead, and the − meter lead goes to the black lead. With the ignition switch on, press the horn button. The meter should register battery voltage. If it does not, the fuse, ignition switch, or the wiring is at fault.
- If the meter does show battery voltage, indicating that the horn trouble lies within the horn itself, and adjustment fails to correct the trouble, replace the horn.



NOTE: Do not loosen the armature mounting since doing so would alter the armature position such that the horn would probably have to be replaced.

SPEEDOMETER AND TACHOMETER

The speedometer and the tachometer are sealed units, which cannot be disassembled. If either fails to work satisfactorily, it must be replaced as a complete unit.

The speedometer and tachometer illumination lights and the indicator lights are independent and can be removed for replacement if necessary.

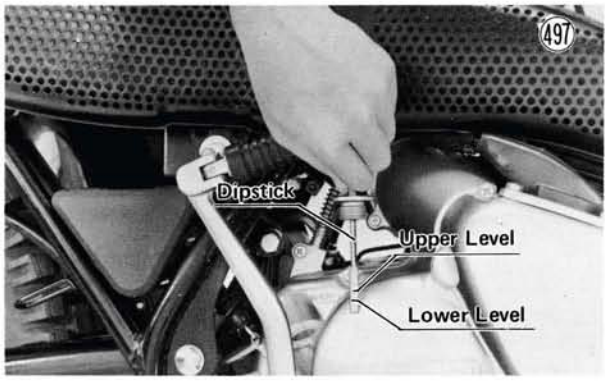
Transmission oil

In order for the transmission and clutch to function properly, maintain the transmission oil at the proper level, and change the oil in accordance with the Periodic Maintenance Chart. Motorcycle opeartion with insufficient, deteriorated, or contaminated transmission oil will cause accelerated wear and may result in transmission seizure.

1) Oil level

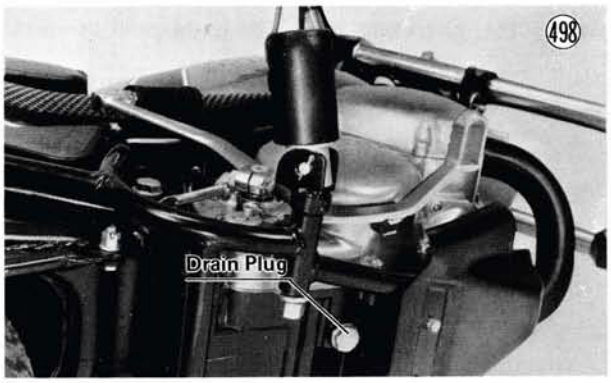
- If the motorcycle has just been used, wait 2 to 3 minutes for all the oil to drain down.
- If the oil has been poured in since the motorcycle was last used, kick the motorcycle over 3 or 4 times with the ignition switch left in the off position. This ensures that the oil will "settle".
- Situate the motorcycle so that it is fully perpendicular to the ground (off its side stand).
- Remove the oil filler opening plug dipstick, and wipe off any oil on the end.
- Insert the dipstick back through the oil filler opening without screwing it in, and then remove it. The oil should be above the lower and below the upper dipstick marks.



- If there is too much oil, remove the excess oil using a syringe or other suitable device.
- If there is too little oil, add the correct amount of oil through the oil filler opening. Fill using the same type and make of oil that already is in the transmission.

2) Oil change

- Warm up the engine thoroughly so that the oil will pick up any sediment and drain easily.
- With the motorcycle fully perpendicular to the ground, place an oil pan beneath the engine, and remove the engine drain plug so that all the transmission oil drains out.

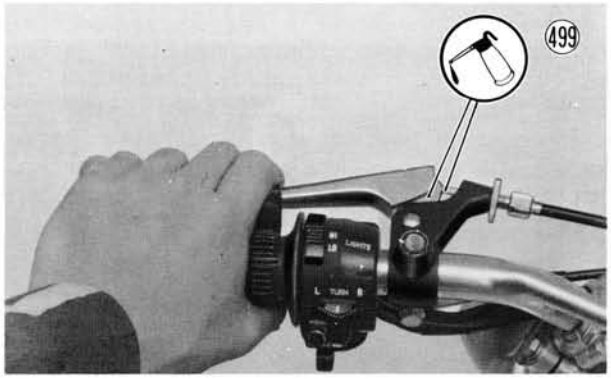


- After the oil has completely drained out, replace the drain plug and gasket, using a new gasket if the old one is deteriorated or damaged. Proper torque for the drain plug is 2.7~3.3 kg-m (19.5~24 ft-lbs).
- Pour in through the oil filler opening in the right engine cover 0.65 ℓ (0.69 US qt) of good quality SE class SAE 10W30 or 10W40 motor oil.

General lubrication

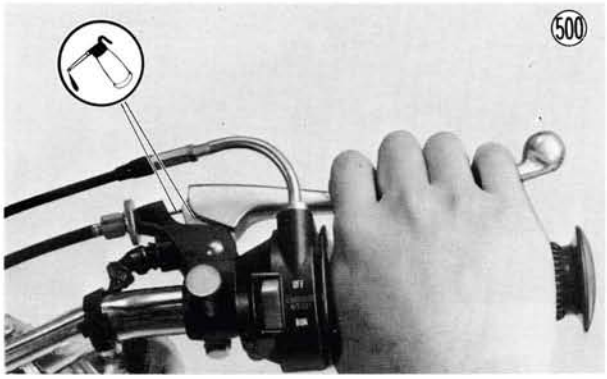
Lubrication of exposed parts subject to rust with either SAE 30 motor oil or regular grease should be carried out periodically and whenever the vehicle has been operated under wet or rainy conditions. Before lubricating each part, clean off any rusty spots with rust remover. Badly rusted nuts, bolts, etc. should be replaced with new ones.

- Slide back the clutch lever dust cover.
- Lubricate the clutch lever pivot and the exposed portion of the clutch inner cable with SAE 30 motor oil.
- Secure the dust cover back into its original position.

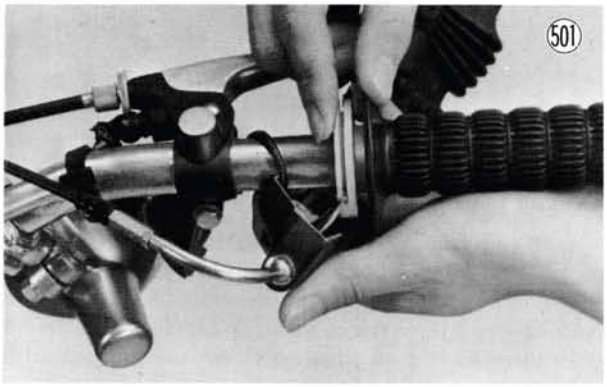


- Slide back the front brake lever dust cover.
- Lubricate the brake lever pivot and the exposed portion of the brake inner cable with SAE 30 motor oil.

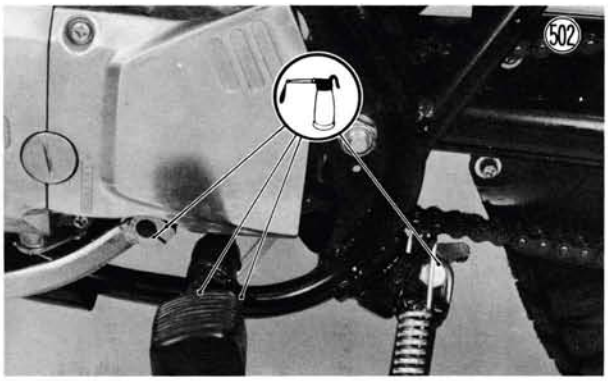
•Secure the dust cover back into its original position.



•Remove the engine stop switch assembly screws (2).
•Apply a light coat of grease to the exposed portion of the throttle grip inner cable.
•Replace the engine stop switch assembly screws.

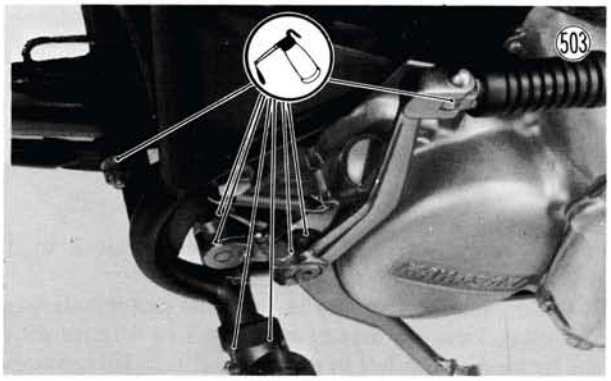


•Wipe off any dirt or grime from around the left footpeg, shift pedal, and side stand.
•Lubricate the exposed metal surfaces around the shift pedal serration and the bolts and nuts for the left footpeg and side stand.
•Wipe off excess lubricant.

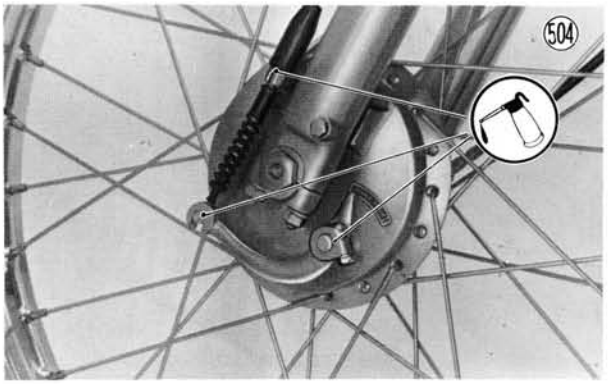


•Wipe off any dirt or grime from around the right footpeg, brake pedal, and kick starter pedal.

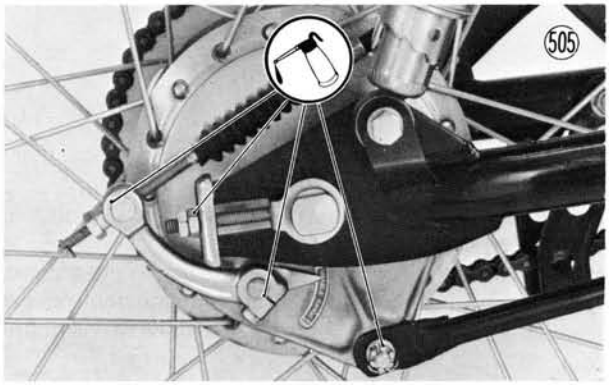
•Lubricate the exposed metal surfaces around the bolts and nuts for the right footpeg, brake pedal, and kick starter pedal.
•Wipe off excess lubricant.



•While pressing down the front brake cable lower dust cover, squirt a few drops of oil onto the front brake inner cable.
•Oil lightly around the camshaft serration and where the cam lever connects to the brake cable.
•Wipe off excess oil.



•Oil lightly the end of each drive chain adjuster, the camshaft serration, and the end of the brake cable.
•Wipe off excess oil.



●Lubricate the front and rear brake cables as shown in the figure.

TORQUE TABLE

Tighten all bolts and nuts to the proper torque using an accurate torque wrench. If insufficiently tightened, a bolt or nut may become damaged or fall off, possibly resulting in damage to the motorcycle and injury to the rider. A bolt or nut which is overtightened may become damaged, strip an internal thread, or break and then fall out. The following table lists the tightening torque for the major bolts and nuts.

When checking the tightening torque of the bolts and nuts, first loosen the bolt or nut by half a turn and tighten to the specified torque.

Supplement

This Supplement is designed to be used in conjunction with the front part of this manual (up to Pg. 165). The maintenance and repair procedures described in this Supplement are only those that are unique to later year units since the first publication of this Service Manual. Complete and proper servicing of later year units therefore requires mechanics to read both this Supplement and the text in front of the Supplement.

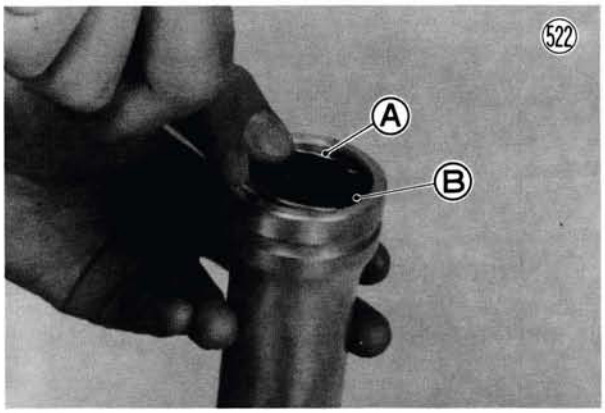
- Slide or push the cylinder ① and its spring ④ out the top of the inner tube.
- Remove the dust seal ⑤ from the outer tube.
- Remove the cylinder base ② out the top of outer tube.
- Hold one finger on the oil seal retainer ⑥ to keep it from flying off while prying the retainer to remove it.



A. Retainer **B. Oil Seal**

- Pull out the oil seal ⑦. It may be necessary to heat the outer tube around the oil seal before pulling it out.

Assembly Notes:

1. Apply liquid gasket to both sides of the gasket ⑪, apply a non-permanent locking agent to the threads of Allen bolt, and tighten it using the front fork cylinder holder handle and adapter (special tools: P/N 57001-183 and 57001-1011) to stop the cylinder from turning. The torque for the Allen bolt is 1.3~2.3 kg-m (9.5~16.5 ft-lbs).

Maintenance

CARBURETOR

Refer to Pgs. 90~95 for other service information not specifically mentioned here.

1. The table below shows the carburetors specifications.

Table 64 Carburetor Specifications

Type	Main Jet	Needle Jet	Jet Needle	Pilot Jet	Throttle Valve Cutaway	Air Screw	Service Fuel Level
VM24SS	95R	O-2	4EJ20-3	30	2.5	1½ turns out	4.5 ± 1 mm

2. Check the fuel level in the carburetor as follows:

Service fuel level measurement and adjustment

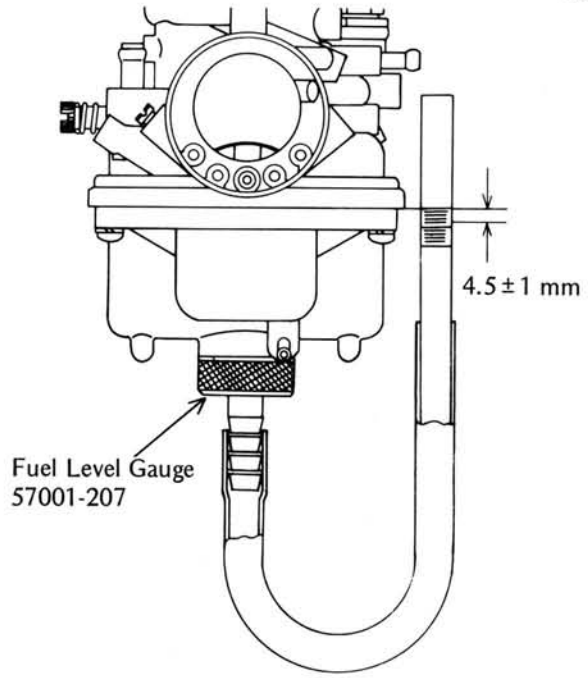
If the motorcycle exhibits symptoms of improper fuel mixture, measure the service fuel level.

- Remove the carburetor, and secure it in a true vertical position on a stand.

WARNING **Check the fuel level in a well-ventilated area, and take ample care that there are no sparks or flame anywhere near the working area.**

- Remove the drain plug from the bottom of the float bowl, and install the fuel level gauge (special tool).
- Keeping the calibrated plastic pipe of the gauge higher than the float bowl, supply fuel for the carburetor by some means (such as a tube from a small fuel container). Wait until the fuel level in the tube settles.
- Keeping the calibrated plastic tube vertical, slowly lower the calibrated plastic tube until the "0" line is even with the bottom edge of the carburetor body.

Fuel Level Measurement (525)



NOTE: Do not lower the "0" line below the bottom edge of the carburetor body. If the calibrated plastic tube is moved upward, the fuel level measurement must be repeated from the beginning.

- Read the service fuel level in the plastic pipe.

The fuel level in the plastic tube should come up to 4.5±1 mm below the edge of the carburetor body.

If the fuel level is incorrect, remove the float bowl and float. Bend the tang on the float a very slight amount to change the fuel level. Bending it up closes the valve sooner and lowers the fuel level; bending it down raises the level (Fig. 526).

After adjustment, measure the service fuel level again, and readjust if necessary.

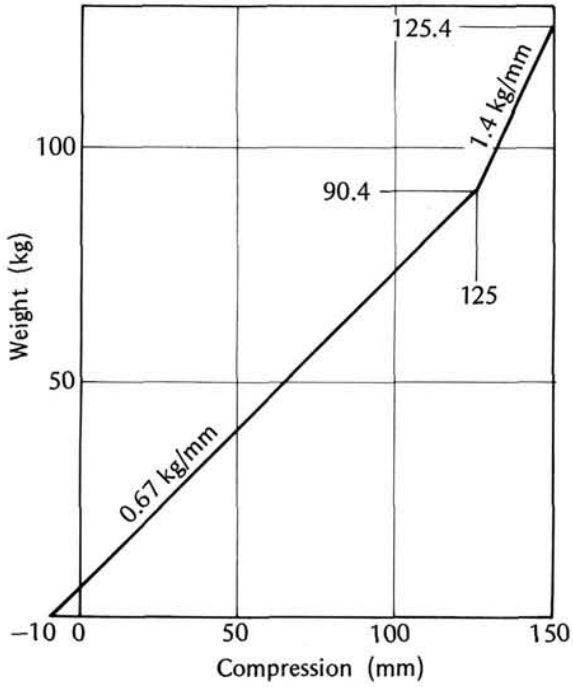
	97.5~ 150 kg	2.0 kg/cm² (28 psi)		

FRONT FORK

The service information for the KE125-A7 is the same as those for the KE125-A6 unless otherwise noted below. See Pgs. 128~131.

Fig. 527 shows the front fork spring force.

Front Fork Spring Force (527)



Fork oil change

To drain out the old oil, remove the drain bolt and gasket from the lower end of the outer tube. With the front wheel on the ground and the front brake fully applied push down on the handlebar a few times to pump out the oil. Install the drain bolt and gasket, remove the top plug from the inner tube, and pour in the type and amount of oil specified in the table. Then check the oil level. If the oil is below the specified level, add oil and re-check the oil level.

NOTE: After the front fork oil is changed, before checking the oil level, pump the front fork several times to expel air from the upper and lower chambers.

Table 68 Fork Oil

Filling fork oil capacity			
Type	When changing oil	After disassembly and completely dry	Oil level
SAE 5W20	about 100 cc	132±2.5 cc	506±2 mm from top of inner tube with spring removed

Fork oil level

To check the fork oil level, first place a jack or stand under the engine so that the front wheel is raised off the ground. Remove the top plug, springs, and spring seat from the inner tube. Insert a rod down into the tube, and measure the distance from the top of the stem head to the oil level. If the oil is below the correct level, add enough oil to bring it up to the proper level, taking care not to overfill.

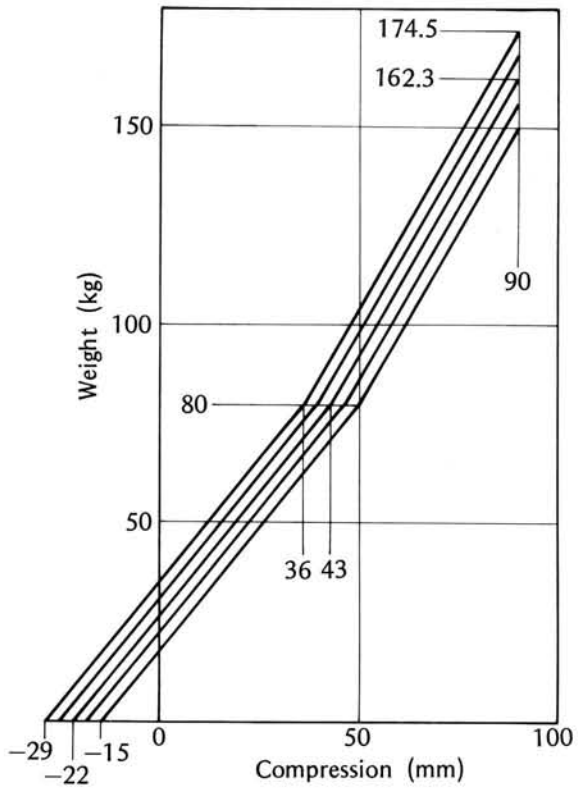
Rear Shock Absorber Spring Force (530)



SPARK PLUG

Refer to Pgs. 143 ~ 144 for other information not specifically mentioned here.

The standard plug (NGK B8ES set to a 0.7~0.8 mm gap) has been selected to match the normal usage of this motorcycle in combined street and highway riding. Unusual riding conditions may require a different spark plug heat range. For slow speed trail riding, it may be necessary to use NGK B7ES plug to avoid fouling.

CAUTION **If the spark plug is replaced with a type other than those mentioned here, make certain the replacement plug has the same thread pitch and reach (length of threaded portion) as the standard plug.**

Table 69 Spark Plug Specifications

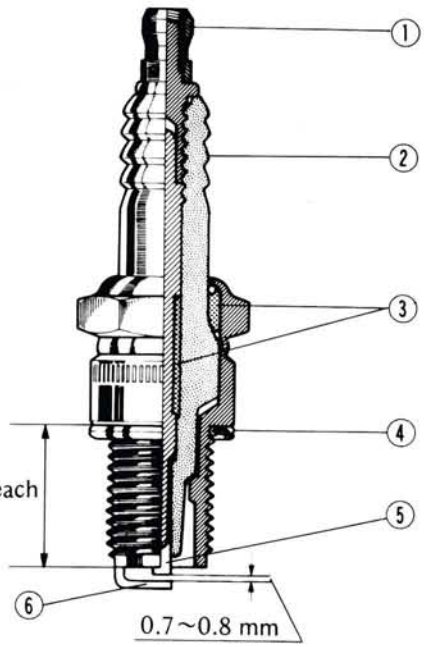
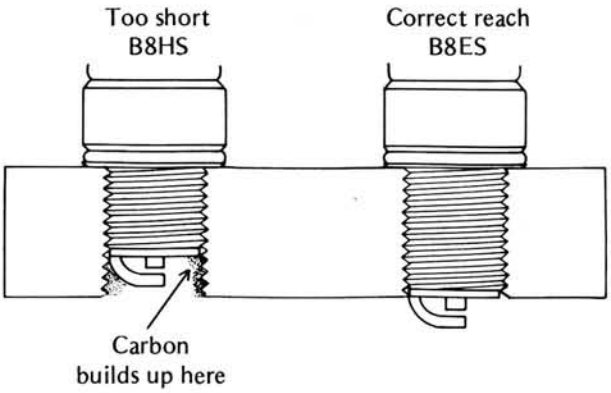
Spark Plug (531)



1. Terminal
2. Insulator
3. Cement
4. Gasket
5. Center Electrode
6. Side Electrode

Plug Reach (532)



If the plug reach is too short, carbon will build up on the plug hole threads in the cylinder head, causing overheating and making it very difficult to insert the correct spark plug later.

If the reach is too long, carbon will build up on the exposed spark plug threads causing overheating, preignition, and possibly burning a hole in the piston top. In addition, it may be impossible to remove the plug without damaging the cylinder head.
